Received 16 September 2003; revised 28 November 2003; accepted 12 February 2004; published 4 June 2004.
[1] In the context of recent observations, microphysical models, and laboratory data, a photochemical model of Titan's atmosphere, including updated chemistry focusing on rate coefficients and cross sections measured under appropriate conditions, has been developed to increase understanding of these processes and improve upon previous Titan photochemical models. The model employs a two-stream discrete ordinates method to characterize the transfer of solar radiation, and the effects of electron-impact, cosmic-ray deposition, and aerosol opacities from fractal and Mie particles are analyzed. Sensitivity studies demonstrate that an eddy diffusion profile with a homopause level of 850 km and a methane stratospheric mole fraction of $2.2 \%$ provides the best fit of stratospheric and upper atmosphere observations and an improved fit over previous Titan photochemical models. Lack of fits for $\mathrm{C}_{3} \mathrm{H}_{8}, \mathrm{HC}_{3} \mathrm{~N}$, and possibly $\mathrm{C}_{2} \mathrm{H}_{3} \mathrm{CN}$ can be resolved with adjustments in aerosol opacity. The model presents a benzene profile consistent with its detection in Titan's stratosphere [Coustenis et al., 2003], which may play an important role in the formation of Titan hazes. An electron peak concentration of $4200 \mathrm{~cm}^{-3}$ is calculated, which exceeds observations by $20 \%$, considerably lower than previous ionosphere models. With adjustments in aerosol opacities and surface fluxes the model illustrates that reasonable fits to existing observations are possible with a single eddy diffusion profile, contrary to the conclusions of previous Titan models. These results will aid in the receipt and interpretation of data from Cassini-Huygens, which will arrive at Titan in 2004 and deploy a probe into Titan's atmosphere in January 2005. ## 1. Introduction

[2] Titan, the only satellite in the Solar System with an extensive atmosphere, has been an object of considerable scrutiny for some time. Titan has a largely $\mathrm{N}_{2}$ atmosphere (90-98\%) [Lindal et al., 1983; Broadfoot et al., 1981] with methane (2-6\%) [Samuelson et al., 1997; Hanel et al., 1981] being the most abundant minor constituent. Methane is dissociated through the transfer of UV solar radiation, photoelectrons, and magnetospheric electrons, which produce highly reactive radical species. These species along with the nitrogen atoms produced through $\mathrm{N}_{2}$ dissociation react to form a bevy of hydrocarbons and nitriles that
characterize Titan's atmosphere. The presence of CO along with the likely influx of micrometeorites into Titan's atmosphere contributes to the collection of oxygen-bearing species that exist in Titan's atmosphere, as well.
[3] A brief historical perspective of relevant observations and previous modeling studies is given first in order to place the present work in proper perspective. The presence of most of the species known to exist in Titan's atmosphere was revealed by the Voyager flybys, which unveiled an object covered with orange-brown hazes. Beneath the haze region the surface was found to have a temperature of 94 K at a pressure of 1.5 bars and a radius of 2575 km [Lindal et al., 1983]. Through these radio occultation measurements, Lindal et al. [1983] were able to infer the temperature profile up to 200 km , which included a tropopause region near 42 km with a temperature of 71 K and a stratospheric

Table 1. List of Neutral and Ionic Compounds Used in the Model

|  | Neutrals | Ions |
| :---: | :---: | :---: |
| H | atomic hydrogen | $\mathrm{H}^{+}$ |
| $\mathrm{H}_{2}$ | molecular hydrogen | $\mathrm{H}_{2}^{+}$ |
| C | atomic carbon | $\mathrm{H}_{3}^{+}$ |
| CH | methylidyne | $\mathrm{H}_{2} \mathrm{O}^{+}$ |
| ${ }^{1} \mathrm{CH}_{2}$ | excited-state methylene | $\mathrm{H}_{3} \mathrm{O}^{+}$ |
| ${ }^{3} \mathrm{CH}_{2}$ | ground-state methylene | $\mathrm{HCO}^{+}$ |
| $\mathrm{CH}_{3}$ | methyl radical | $\mathrm{CH}_{3}^{+}$ |
| $\mathrm{CH}_{4}$ | methane | $\mathrm{CH}_{4}^{+}$ |
| $\mathrm{C}_{2}$ | molecular carbon | $\mathrm{CH}_{5}^{+}$ |
| $\mathrm{C}_{2} \mathrm{H}$ | ethynyl radical | $\mathrm{C}_{2} \mathrm{H}_{2}^{+}$ |
| $\mathrm{C}_{2} \mathrm{H}_{2}$ | acetylene | $\mathrm{C}_{2} \mathrm{H}_{3}^{+}$ |
| $\mathrm{C}_{2} \mathrm{H}_{3}$ | vinyl radical | $\mathrm{C}_{2} \mathrm{H}_{4}^{+}$ |
| $\mathrm{C}_{2} \mathrm{H}_{4}$ | ethylene | $\mathrm{C}_{2} \mathrm{H}_{5}^{+}$ |
| $\mathrm{C}_{2} \mathrm{H}_{5}$ | ethyl radical | $\mathrm{C}_{2} \mathrm{H}_{6}^{+}$ |
| $\mathrm{C}_{2} \mathrm{H}_{6}$ | ethane | $c_{\text {- }} \mathrm{C}_{3} \mathrm{H}_{3}^{+}$ |
| $\mathrm{C}_{3} \mathrm{H}_{2}$ | propadienylidene | $\mathrm{C}_{3} \mathrm{H}_{5}^{+}$ |

|  | Neutrals | Ions |
| :--- | :--- | :--- |
| $\mathrm{CH}_{2} \mathrm{OH}$ | hydroxymethyl radical |  |
| $\mathrm{CH}_{3} \mathrm{O}$ | methoxy radical |  |
| $\mathrm{CH}_{3} \mathrm{OH}$ | methanol |  |
| $\mathrm{CH}_{2} \mathrm{CO}$ | ketene |  |
| $\mathrm{CH}_{3} \mathrm{CO}$ | acetyl radical |  |
| $\mathrm{CH}_{3} \mathrm{CHO}$ | ethylene oxide |  |
| $\mathrm{C}_{2} \mathrm{H}_{4} \mathrm{O}$ | oxirane |  |

inversion layer, increasing temperatures to 170 K at 200 km . Further analysis of Voyager Infrared Spectrometer (IRIS) and Voyager Ultraviolet Spectrometer (UVS) data yielded much of what is known about the distribution of constituents in Titan's atmosphere listed as shown in Table 1. However, Voyager did not uncover much about the middle and upper atmosphere. An exospheric temperature of 186 K was obtained by Smith et al. [1982]. But, beyond some observations of $\mathrm{CH}_{4}$ and $\mathrm{C}_{2} \mathrm{H}_{2}$ [Smith et al., 1982], little is known about the vertical distribution of Titan's constituents throughout the atmosphere, largely due to the opacity provided by $\mathrm{CH}_{4}$ and Titan's hazes. In fact, the hazes themselves remain largely a mystery. Voyager revealed an opaque haze region consisting of a main haze layer around 220 km and a detached haze layer at $300-350 \mathrm{~km}$ [Rages and Pollack, 1983]. However, the precise source of this region and its composition is left to speculation.
[4] In the upper atmosphere the absorption of solar EUV radiation produces an ionosphere that interacts with Saturn's magnetosphere and the solar wind. This interaction is not constant as variations in solar wind pressure cause a compression of the magnetosphere, resulting in Titan being outside of the magnetosphere part of the time. However, upon Voyager 1's arrival, Titan was inside Saturn's magnetosphere, and Voyager observed a Venus-like interaction between Titan and the magnetosphere with no bow shock [Neubauer et al., 1984; McNutt and Richardson, 1988], allowing Titan to mainly interact with precipitating magnetospheric electrons along with photoelectrons produced within Titan's ionosphere. Early analysis revealed a variation in electron peak concentration with derived upper limits of $3000 \mathrm{~cm}^{-3}$ at the evening terminator and $5000 \mathrm{~cm}^{-3}$ at the morning terminator [Lindal et al., 1983]. Bird et al. [1997] reanalyzed Voyager data to obtain an electron peak density of $2400 \pm 1100 \mathrm{~cm}^{-3}$ at $1180 \pm 150 \mathrm{~km}$ at the evening terminator at a solar zenith angle near $90^{\circ}$.
[5] The data presented by the Voyager flybys provided the impetus for the construction of photochemical models that have attempted to investigate how chemical species are distributed in Titan's atmosphere. The first extensive photochemical model after the Voyager flybys was developed by Yung et al. [1984], which made use of a large reaction set and early analyses of Voyager data [Hanel et al., 1981; Maguire et al., 1981; Kunde et al., 1981; Samuelson et al., 1983]. Toublanc et al. [1995] and Lara et al. [1996] took advantage of improved analysis of Voyager observations [Coustenis et al., 1989, 1991] and subsequent ground-based millimeter observations [Tanguy et al., 1990; Hidayat et al., 1997] to infer different profiles of the eddy diffusion coefficient. Toublanc et al. [1995] included a Monte Carlo treatment of the transfer of solar radiation in the atmosphere, while Lara et al. [1996] included physically based water ablation profiles to account for the oxygen source from micrometeor-
ites. Keller et al. [1992] and Fox and Yelle [1997] used neutral photochemical models as a basis for the construction of ionosphere models. Galand et al. [1999] used the Toublanc et al. [1995] photochemical model to investigate diurnal effects on Titan's ionosphere, while Banaszkiewicz et al. [2000] combined the Lara et al. [1996] model with an investigation of charged particle chemistry to construct a coupled model of Titan's atmosphere and ionosphere.
[6] Despite these investigations many questions regarding Titan chemistry still remain unanswered. Photochemical models have been unable to simultaneously fit the vertical profiles of observed species. Furthermore, although many microphysical models have been developed [e.g., Rannou et al., 1995], the chemical sources of Titan's haze layer are still quite unknown.
[7] The low temperatures which characterize outer planetary atmospheres, and Titan, in particular, have prompted many measurements of reaction rates and cross sections at low temperatures which were not included in previous Titan photochemical models. Microphysical modeling and analysis of Voyager photometric and polarimetric observations and albedo data have suggested the fractal nature of Titan haze whose scattering effects differ than those considered in previous one-dimensional Titan photochemical models (the two-dimensional model of Lebonnois et al. [2001] does consider fractal haze particles). With this in mind and in the context of preparation for the retrieval and interpretation of data from the upcoming Cassini-Huygens investigation of Titan, a one-dimensional steady state photochemical model has been constructed. This model computes the mole fraction for 80 neutrals and 33 ions, shown in Table 2, from the surface to 1600 km , while self-consistently calculating the total number density as a function of the mean molecular weight. The model incorporates a two-stream discrete ordinates scattering model, differing from the scattering treatment of previous Titan models, and includes dissociation via photoelectrons from $15-1000 \mathrm{eV}$, magnetospheric electrons, and cosmic rays, along with solar radiation from 50-3000 A. A multicomponent treatment of molecular diffusion is included along with sensitivity studies of various eddy diffusion profiles. The sensitivity studies include the analysis of constituent profiles generated by 100 eddy diffusion profiles, increasing through the stratosphere in varying degrees, with homopause levels ranging from 600 km to 1150 km .
[8] This paper discusses the details of the photochemical model, including the equations and inputs used to calculate constituent densities in sections 2 and 3. A discussion of the important free parameter of eddy diffusion is provided, detailing the basis for the profiles used in the sensitivity studies regarding Titan's homopause level. The chemical mechanisms, which govern the distribution of hydrocarbon, oxygen, and nitrile neutrals as well as ions in Titan's atmosphere, are discussed in section 4. Sensitivity studies regarding eddy diffusion and aerosol opacity are examined in section 5, along with a discussion on constituent profiles. Finally, conclusions are detailed in section 6.

## 2. Model Description

[9] To examine the physical and chemical processes that shape the distribution of constituents with altitude in Titan's
atmosphere, a one-dimensional photochemical model is developed. This photochemical model solves the steady state altitude-dependent continuity-diffusion equation in spherical coordinates

$$
\begin{equation*}
P_{i}-L_{i}=\frac{1}{r^{2}} \frac{\partial\left(r^{2} \Phi_{i}\right)}{\partial r} \tag{1}
\end{equation*}
$$

where $P_{i}$ is the chemical production rate of species $i, L_{i}$ is the chemical loss rate, the radius $r=\left(R_{0}+z\right)$, where $R_{0}$ is the radius of Titan and $z$ is the altitude, and $\Phi_{i}$ is the vertical flux, which can be expressed as

$$
\begin{align*}
\Phi_{i}(z)= & -D_{i}\left[n \frac{\partial \xi_{i}}{\partial z}+\xi_{i} \frac{\partial n}{\partial z}+\left[1+\left[1-\xi_{i}\right] \alpha_{i}\right] \frac{n \xi_{i}}{T} \frac{\partial T}{\partial z}+\frac{n \xi_{i}}{H_{i}}\right] \\
& -K n \frac{\partial \xi_{i}}{\partial z} \tag{2}
\end{align*}
$$

where $n$ is the total number density, $\xi_{i}$ is the mole fraction, $D_{i}$ is the molecular diffusion coefficient, $K$ is the eddy diffusion coefficient, $\alpha_{i}$ is the thermal diffusion coefficient, $T$ is the temperature, and $H_{i}$ is the scale height

$$
\begin{equation*}
H_{i}=\frac{R T}{m_{i} g}, g=\frac{G M}{r^{2}} \tag{3}
\end{equation*}
$$

with $R$ as the gas constant, $m_{i}$ as the molecular weight of species $i, g$ as the gravity, $G$ as the gravitational constant, and $M$ representing Titan's mass. The total number density as a function of mean molecular weight can be determined from the equation of hydrostatic equilibrium,

$$
\begin{equation*}
\frac{d p}{d z}=-\rho g \tag{4}
\end{equation*}
$$

where $p$ is the pressure and $\rho$ is the mass density $=n m$, where $m=\sum_{i} m_{i} \zeta_{i}(z)$, the mean molecular weight at altitude $z$, and the gas law

$$
\begin{equation*}
p[f+1]=n k T \tag{5}
\end{equation*}
$$

where $k$ is Boltzmann's constant and $f$ is a factor marking the departure from gas ideality, as Titan's atmosphere exhibits non-ideal characteristics near its surface [Lindal et al., 1983]. Atmospheric parameters that are inputs into the model are the surface pressure $p_{0}=1496 \mathrm{mb}$ [Lindal et al., 1983] and the non-ideality profile and temperature profile (Figure 1a), modeled by Yelle et al. [1997] and used for all studies related to the Huygens probe.
[10] These equations are finite differenced (see Appendix A) and solved through the reduced Jacobian solver method [Sandilands and McConnell, 1997] where the species in Table 2 are divided into two families, representing the neutrals and the ions. The structure of the model is laid out in Figure 2. The primary input parameters - the solar flux and cross sections combined with the thermal profile - are used to calculate the next group of parameters located in the first box. The calculation of the radiation field then follows, producing photolysis rates for absorbing species. The continuity-diffusion equation is then inverted

Table 2. Observations of Constituents in Titan's Atmosphere

| Species | Altitude, km | Instrument | Observation | References |

\frac{\Delta \xi}{\xi}<10^{-4} \\
\frac{\Delta n}{n}<10^{-4}
\end{array}\right.
$$

The resultant nominal total number density profile is shown in Figure 1b.

## 3. Model Parameters

### 3.1. Radiation Field

### 3.1.1. Solar Flux Input

[11] During the Voyager 1 flyby of Titan in November 1980, the solar flux output was near the maximum of its 11-year cycle, amplifying the effect of solar radiation on the

Figure 1. a) Temperature profile and non-ideality factor from Yelle et al. [1997]. b) Calculated total number density in Titan's atmosphere.
atmosphere. However, most of the stable constituents in Titan's atmosphere have lifetimes longer than one solar cycle in the stratosphere and are thus less sensitive to the changes in solar flux over the course of that cycle in that region. Thus the solar flux for moderate solar conditions obtained by The Solar-Stellar Irradiance Comparison Experiment (SOLSTICE) [Woods et al., 1996] on the Upper Atmosphere Research Satellite (UARS) from 1150-3000 A and an EUV flux, calculated using the EUVAC model [Richards et al., 1994] for solar conditions associated with a 10.7 cm radio solar flux of $130\left(\times 10^{-22} \mathrm{~W} \mathrm{~m}^{-2} \mathrm{~Hz}^{-1}\right)$, is used to calculate neutral densities in the nominal model. However, in the upper atmosphere above $\sim 0.01 \mu$ bar, lifetimes for most constituents are considerably shorter. Sensitivity to solar flux for many of these constituents is discussed in section 5.2, in which simulations are run for solar minimum, solar maximum, and moderate solar conditions. Due to the short ion chemical lifetimes, profiles for charged particles in the solar maximum case are considered

Figure 2. Layout of the structure of the model.
for the nominal model. In the solar maximum case, an EUV flux for $\mathrm{F} 10.7=233$ and the 81 -day average 10.7 cm radio solar flux (F10.7A) equal to 211.9, which matches the solar conditions during the Voyager flyby, is used to calculate the distribution of species. The incident solar flux is calculated with a zenith angle of $58^{\circ}$, corresponding to the zenith angle representing a globally averaged incident flux in November 1980.
[12] The scattering contribution to the solar flux is calculated through a two-stream discrete ordinates algorithm detailed by Edgington et al. [1998]. The contributions of solar radiation, direct and scattered flux, for three characteristic wavelengths are shown in Figure 3. In the EUV region, scattering does not play a major role, shown in the $800 \AA$ example, as nitrogen absorption prevents the penetration of photons to deeper regions where scattering would have a larger effect. In the $1700 \AA$ example, radiation penetrates further into the atmosphere, allowing some backscattering to take place. In the denser regions, the effect

Figure 3. The direct solar flux and diffuse contribution as a function of altitude for $800 \AA, 1700 \AA$, and $3000 \AA$ intensities.

Figure 4. a) Radial electron fluxes from T. Cravens (personal communication, 1998) for various electron energies. b) Electron density profile in Titan's stratosphere (solid line) and molecular nitrogen dissociation as a result of cosmic ray deposition (long dashed line).
of scattering increases. At $3000 \AA$, the high single scattering albedo results in similar levels of direct and diffuse radiation throughout the atmosphere, with scattering dominating the solar input below 300 km .

### 3.1.2. Electron Input

[13] The solar flux while ionizing molecules also creates photoelectrons in the process. These photoelectrons play a significant role in the radiation field by providing an additional source of energy through which chemistry is induced. In their study of Titan's ionosphere, Gan et al. [1992] calculated photoelectron fluxes through Titan's atmosphere as a function of electron energy. On the basis of this study, the radial fluxes of photoelectrons from $15-$ 100 eV , for a solar zenith angle of 60 degrees is adopted for altitudes from $725-1600 \mathrm{~km}$ (T. Cravens, personal communication, 1998). The radial fluxes for some of these electrons are shown in Figure 4a. Considering the input from Saturn's magnetosphere, Keller et al. [1992] calculated the ion production rates of $\mathrm{N}_{2}^{+}, \mathrm{N}^{+}$, and $\mathrm{CH}_{4}^{+}$, the ions that begin Titan ion chemistry, due to magnetospheric electron impact. These rates are also considered in the model.

### 3.1.3. Cosmic Rays

[14] The deposition of cosmic rays in Titan's stratosphere can be an important source of nitrile formation through cosmic ray-induced $\mathrm{N}_{2}$ dissociation. Cosmic ray input in Titan's atmosphere is treated using the model of local energy deposition described by Atreya et al. [1995], assum-
ing zero magnetic rigidity for Titan, under moderate solar conditions. The cascading penetration of energy deposition analyzed by Capone et al. [1983] is neglected, amounting to a possible underprediction of $\mathrm{N}_{2}$ dissociation of a factor $\sim 2$, according to Lellouch et al. [1994]. The total ionization rate calculated is assumed to equal the $\mathrm{N}_{2}$ ionization rate and is scaled for the dissociation and ionization rate of $\mathrm{N}_{2}$ and other species by a factor relating the peak absorption cross section via electron impact of that species with the $\mathrm{N}_{2}$ absorption cross section at that wavelength. Thus, for $\mathrm{X}+e^{-} \rightarrow \mathrm{j}^{(+)}$, where j is a neutral or ion,

$$
\begin{equation*}
P_{j}^{X}=\frac{\sigma_{X}\left(E_{j}^{\text {peak }}\right) q_{j}}{\sigma_{N_{2}}\left(E_{j}^{\text {peak }}\right) q_{i o n}^{N_{2}}} Q_{N_{2}} \xi_{X}=J_{j} n \xi_{X} \tag{6}
\end{equation*}
$$

where, $P_{j}^{X}$ is the production rate of species j from destruction of $\mathrm{X}, \sigma_{j}$ is the electron impact absorption cross section of species $j, E_{j}^{\text {peak }}$ is the electron energy of peak absorption for species $\mathrm{j}, q_{j}$ is the quantum yield of species j from destruction of $\mathrm{X}, q_{\text {ion }}^{N_{2}}$ is the total ionization quantum yield of $\mathrm{N}_{2}$ for electron impact, $Q_{N_{2}}$ is the calculated total ionization rate of $\mathrm{N}_{2}$ from cosmic ray impact, and $J_{j}$ is the coefficient of production from destruction of X .

### 3.2. Photochemistry

[15] The chemical production term in the continuity equation (1) is given by

$$
\begin{equation*}
P_{i}=\sum_{j} \sum_{k} k_{j k} n^{2} \xi_{j} \xi_{k}+\sum_{l} J_{l}^{i} n \xi_{l} \tag{7}
\end{equation*}
$$

where $k_{j k}$ is the rate coefficient of the reaction in which species $j$ and species $k$ react to form species $i$, while

$$
\begin{equation*}
J_{l}^{i}(z)=\int_{\lambda} \sigma_{l}^{a b s} I(z, \lambda) q_{i}(\lambda) d \lambda \tag{8}
\end{equation*}
$$

where $q_{i}(\lambda)$ is the quantum yield, representing the probability that the photolysis of $l$ will produce $i$. The expression $k_{j k} n^{2} \xi_{j} \xi_{k}$ represents the production rate of $i$ resulting from the two-body reaction of $j$ and $k$, and $J_{l n} n \xi_{l}$ is the production rate of $i$ resulting from the photolysis of $l$. The chemical term for species $i$, on the other hand, is dependent on the mixing ratio of $i$, as the loss rate of a species is affected by its abundance

$$
\begin{equation*}
L_{i}=\sum_{j} k_{i j} n^{2} \xi_{i} \xi_{j}+J_{i} n \xi_{i} \tag{9}
\end{equation*}
$$

$k_{i j}$ is the rate coefficient of the reaction of reactant $i$ with some reactant $j$, with $k_{i j} n^{2} \xi_{i} \xi_{j}$ expressing the reaction rate of $i$ and $j$. The photolysis rate of $i$ is $J_{i} n \xi_{i}$.
[16] For three-body pressure dependent reactions, where the two reactants react with the background atmosphere, $k_{j k}$ is often given in terms of a low-pressure rate $k_{0}$ and a highpressure rate $k_{\infty}$ where

$$
\begin{equation*}
k_{j k}=\frac{k_{0} k_{\infty} n}{\left(k_{0} n+k_{\infty}\right)} \tag{10}
\end{equation*}
$$

Meanwhile, the production rate due to the deexcitation of an excited constituent is $k_{j} n \xi_{j}$, where $k_{j}$ is the deexcitation rate of constituent $j$.
[17] The set of reactions used in the model is displayed in Table 3. The reaction rates chosen are the rates calculated or measured under the conditions most representative of Titan's atmosphere. The most important of these conditions is temperature. The rate of a reaction can vary by many orders of magnitude over the span of 100 K in temperature, which can have a large effect on the overall chemistry of the atmosphere. The bulk of chemistry in Titan's atmosphere occurs in the region where atmospheric temperatures range between about 130 K and 180 K . So, rate coefficient measurements that are applicable at or near these temperatures are favored over rate measurements that are applicable at room temperature, for example. The pressure at which the rate was measured and the bath gas used is also taken into consideration.
[18] The absorption cross sections and quantum yields which are used in (7) to calculate photolysis rates are referenced in Table 4. Many of these cross sections can also vary significantly with temperature, and thus low temperature cross sections, where available, are used. For Rayleigh scattering, the cross section is

$$
\begin{equation*}
\sigma_{i}^{\text {Ray }}=\frac{32 \pi^{3} \alpha_{i}^{2}\left[\frac{6+3 \delta_{i}}{6-7 \delta_{i}}\right]}{3 \lambda^{4}} \tag{11}
\end{equation*}
$$

where $\alpha_{C H_{4}}=25.6 \times 10^{-25}, \delta_{C H_{4}}=0, \alpha_{N_{2}}=3.96 \times 10^{-25}$, and $\delta_{N_{2}}=0.03$ [Allen, 1976].
[19] Microphysical models matched with geometric albedo observations [e.g., McGrath et al., 1998] have suggested that Titan aerosols in the main haze layer are likely fractal in nature. Aerosol opacities for fractal particles were taken from Lebonnois et al. [2001], assuming aerosol single scattering albedos calculated from scattering and extinction efficiency factors from Rannou et al. [1995]. Haze opacity profiles for Mie particles from Rannou et al. [1995] were also tested.
[20] Charged particles are assumed to be governed solely through chemical processes with the assumption of charge neutrality. The electron temperature is taken from Keller et al. [1992] model A.

### 3.3. Condensation

[21] Due to the very low temperatures reached in Titan's tropopause and lower stratosphere, many gases become saturated and proceed to condense according to their saturation vapor pressures. The saturation laws governing condensing species are taken from Allen and Nelson [1998] for $\mathrm{CH}_{4}$ above $90 \mathrm{~K}, \mathrm{C}_{2} \mathrm{H}_{2}$, and $\mathrm{C}_{2} \mathrm{H}_{4}$, Moses et al. [1992] for other hydrocarbons, Washburn [1924] for $\mathrm{H}_{2} \mathrm{O}$, and Sagan and Thompson [1984] for $\mathrm{HC}_{3} \mathrm{~N}$. Vapor pressures for other compounds are determined by fitting the lowest two points in the vapor pressure table from Weast et al. [1987] for the expression $\ln p(z)=A+\frac{B}{T(z)}$. This process is taken into account in the chemical side of equation (1) where for condensing species,

$$
\begin{equation*}
P_{i}-L_{i}-\gamma_{i}=\frac{1}{r^{2}} \frac{\partial\left(r^{2} \Phi_{i}\right)}{\partial r} \tag{12}
\end{equation*}
$$

where $\gamma_{i}$ is the condensation factor of species $i$. The condensation factor is assumed to dominate in regions of condensation, forcing the constituent mixing ratio profile to follow the profile associated with its saturation vapor pressure. This is done by setting the condensation factor

$$
\begin{equation*}
\gamma_{i}=\left[A n\left[\xi_{i}-\xi_{i}^{s a t}\right]\right]^{p} \tag{13}
\end{equation*}
$$

where $\xi_{i}^{\text {sat }}$ equals the saturation mole fraction, $A \gg P_{i}, L_{i}$, and $p$ is a constant $\approx 1$ to smooth the transition between condensation and non-condensation regions.
[22] As evident in equation (4) the total number density is dependent on the mean mass of the atmosphere, which will be affected by the distribution of the most abundant constituents. Thus condensation must be taken into account in the mean mass calculation in a similar fashion as the mole fractions in equation (13), by forcing $m(z)=m^{\text {sat }}(z)$ in condensing regions, where

$$
\begin{equation*}
m^{s a t}(z)=\sum_{i} m_{i} \min \left(\xi_{i}, \xi_{i}^{s a t}\right) \tag{14}
\end{equation*}
$$

### 3.4. Boundary Conditions

[23] The boundary conditions for the model are presented in Table 5. At the lower boundary, the mole fractions for $\mathrm{H}_{2}$ and CO are set to their observed quantities in the stratosphere, while $\mathrm{CH}_{4}$ assumes a mixing ratio profile consistent with the saturation model of Samuelson et al. [1997], with a surface mole fraction of $5.6 \%$ and a supersaturation of 1.37. $\xi_{N_{2}}$ follows as $1-\sum \xi_{i}, i \neq \mathrm{N}_{2}$ throughout the model. The total number density is set to $1.2 \times 10^{20} \mathrm{~cm}^{-3}$ at the lower boundary, associated with a pressure of 1496 mb , a temperature of 94 K , and a non-ideality factor of 0.0347 . At the upper boundary, $\Phi_{i}=0$ is assumed for most species, although $\Phi_{\mathrm{H}_{2} \mathrm{O}}=-5.0 \times 10^{6}$ molecules $\mathrm{cm}^{-2} \mathrm{~s}^{-1}$ is adopted for $\mathrm{H}_{2} \mathrm{O}$, accounting for the influx of water molecules arising from micrometeorites [Feuchtgruber et al., 1997]. For H and $\mathrm{H}_{2}$, the escape flux is dependent on the density of these constituents that are being solved. Thus the boundary condition accounting for escape of H , $\mathrm{H}_{2}$ is expressed in terms of velocity
$w_{i}\left(\tilde{r}_{N}\right)=-D_{i}\left[\frac{1}{\xi_{i}} \frac{\partial \xi_{i}}{\partial z}+\frac{1}{n} \frac{\partial n}{\partial z}+\left[1+\alpha_{i}\right] \frac{1}{T} \frac{\partial T}{\partial z}+\frac{1}{H_{i}}\right]-K \frac{1}{\xi_{i}} \frac{\partial \xi_{i}}{\partial z}$.

The top of the model is assumed to be the exobase, where the effusion velocity from Jeans escape is given as

$$
\begin{equation*}
w_{e}=\sqrt{\frac{k T}{2 \pi m}}\left[1+E_{e}\right] e^{-E_{e}} \tag{16}
\end{equation*}
$$

where $E_{e}=\frac{r_{e}}{H_{e}}$. Thus $w_{H}=2.72 \times 10^{4} \mathrm{~cm} \mathrm{~s}^{-1}$ and $w_{H_{2}}=$ $7000 \mathrm{~cm} \mathrm{~s}^{-1}$.

### 3.5. Vertical Transport

### 3.5.1. Molecular Diffusion

[24] Molecular diffusion coefficients are often provided as measurements of diffusivity in a medium consisting of two constituents. Atmospheres, however, are not binary

mixtures of gases, but rather are composed of many constituents. For an atmosphere dominated by one constituent, binary coefficients involving that major constituent and a minor constituent are sufficient for calculating the molecular diffusion coefficient of that given minor constituent. However, an atmosphere with a minor constituent that makes up a significant portion of the bulk gas requires a multicomponent treatment. Wilke [1950] provides a convenient approximation for the diffusion of gas in a multicomponent mixture of J gases

$$
\begin{equation*}
D_{i}=\frac{1-\xi_{i}}{\sum_{j=1, j \neq i}^{J} \frac{\xi_{j}}{D_{i j}}} \tag{17}
\end{equation*}
$$

where $D_{i j}$ are the binary diffusion coefficients and $\xi_{i}$ is the mole fraction for species $i$. This formulation, which is good to about $10 \%$ for multicomponent systems where the individual diffusion coefficients are not sensitive to composition changes [Wilke, 1950], is useful for Titan where methane increases, due to diffusive separation, in the heterosphere, exceeding $20 \%$ above 1400 km [Strobel et al., 1992]. Unfortunately, the measurements of binary coefficients have been conducted for only a select group of molecules. The diffusion coefficient follows the form of

$$
\begin{equation*}
D=\frac{A T^{s}}{n} \tag{18}
\end{equation*}
$$

where $T=$ temperature and $n=$ bulk gas density. The binary gas mixtures pertinent to Titan that have been measured or empirically calculated are shown in Table 6. In the absence
of measurements, empirical correlations are often used, on the basis of the physical parameters of the given molecules.
[25] Thermal diffusion, which typically affects light gases, is given by the term in equation (2)

$$
\left[1-\xi_{i}\right] \alpha_{i} \frac{n \xi_{i}}{T} \frac{\partial T}{\partial z}
$$

where $\alpha_{i}$ is the thermal diffusion coefficient. In the model, $\alpha_{H}=\alpha_{H_{2}}=-0.38$ is adopted [Banks and Kockarts, 1973], while for all other species $\alpha=0$.

### 3.5.2. Eddy Diffusion

[26] Owing to the complexity involved in relating microscopic turbulent processes to macroscopic transport, the eddy diffusion coefficient acts as a free parameter that must be estimated to match constituent observations. This task is relatively trivial for a completely inert species (e.g., argon), as the point where the constituent profile changes from well-mixed to diffusively separated marks the homopause where the eddy diffusion coefficient is equal to the molecular diffusion coefficient of the constituent. Unfortunately, there is no known vertical profile of such a species for Titan. Methane, however, is largely inert and is distributed largely through diffusive processes, as shown in Figure 5a. Thus the methane distribution can be used as a proxy for the determination of the homopause level. In the lower atmosphere, chemistry plays a major role for many species. However, HCN is largely formed in the upper atmosphere and transported to lower altitudes. In much of the lower regions of the atmosphere the eddy diffusion time constant is much smaller than the HCN chemical time constant (Figure 5b), and the millimeter observations of Tanguy et al. [1990] and Hidayat et al. [1997] provide a vertical

Table 6. Binary Molecular Diffusion Coefficients Used in the Model

profile for HCN in this region. These factors make HCN a good candidate for constraining the eddy diffusion profile in the lower atmosphere.
[27] Observations of $\mathrm{CH}_{4}$ in the upper atmosphere were provided by Smith et al. [1982], who analyzed the Voyager ultraviolet spectrometer (UVS) observations and obtained mole fractions of $6 \pm 1 \%$ at 1000 km and $8 \pm 3 \%$ at 1130 km . However, the reanalysis of Voyager data by R. J. Vervack et al. (New perspectives on Titan's upper atmosphere from a reanalysis of the Voyager 1 UVS solar occultations, submitted to Icarus, 2003) (hereinafter referred to as Vervack et al., submitted manuscript, 2003) suggested a methane mixing ratio profile that might decrease with altitude, contrary to what would be expected from diffusive separation. Such a profile might be possible through a large chemical sink for $\mathrm{CH}_{4}$, as suggested by Lara et al. [1999], but such a sink would most likely require much larger electron densities that what has been observed, as discussed in section 5.7. The authors argue that this profile may be the result of misassignment of $\mathrm{CH}_{4}$ absorption to other species above 1050 km . With the large error bars and lack of coverage below the nanobar region, these results are unable to yield any firm conclusions about the homopause level, although the authors favor a high homopause level. Strobel et al. [1992], in their analysis of Voyager UVS solar occultation and airglow data, also infer a high homopause level around 1000 km. However, Steiner and Bauer [1990] in their study of diffusive processes on Titan, presented an analytical eddy profile corresponding to a homopause level of 660 km .
[28] The UVS reanalysis also points out a discrepancy with the Smith et al. [1982] $\mathrm{C}_{2} \mathrm{H}_{2}$ observations, retrieving
up to three orders of magnitude less acetylene in the upper atmosphere than was suggested by the Smith et al. [1982] observations. This finding is supported by photochemical models, which have not determined a mechanism to form upper atmospheric $\mathrm{C}_{2} \mathrm{H}_{2}$ at such high densities as suggested by Smith et al. [1982].
[29] The millimeter observations of Hidayat et al. [1997] and Tanguy et al. [1990] are in decent agreement with each other over the lower 200 km of the atmosphere. However, above this level they diverge, with Hidayat et al. [1997] observing an approximately uniform HCN mixing ratio profile while Tanguy et al. [1990] observed a profile increasing with altitude. The recent Marten et al. [2002] observations corroborate the finding of Tanguy et al. [1990] that HCN increases in mole fraction throughout the stratosphere. To determine the nominal eddy diffusion profile, the fitting of the Smith et al. [1982] $\mathrm{CH}_{4}$ observations in the upper atmosphere and the HCN observations of Hidayat et al. [1997] and Tanguy et al. [1990] are used as a guideline. Considering this set of observations, 100 monotonically increasing, randomly generated eddy diffusion coefficients are used to determine the best fits for the $\mathrm{CH}_{4}$ and HCN observations. These profiles are generated by obtaining diffusion coefficients at 12 altitude levels, determined by calculating a randomly generated positive slope from the previous altitude level within a predetermined range. The eddy diffusion coefficient at the lower boundary is randomly chosen between $100-10000 \mathrm{~cm}^{2} \mathrm{~s}^{-1}$. The results of the bestfit profiles are then compared to determine which profile fits the remaining observational constraints, with slight adjustments made to achieve a better fit. The resulting nominal profile (NOM) along with the Steiner and Bauer [1990] profile (SB) is shown in Figure 6a, corresponding to a homopause level of 850 km . This process was repeated, replacing the Smith et al. [1982] results with those from the Vervack et al. (submitted manuscript, 2003) nominal $\mathrm{CH}_{4}$ profiles up to 1050 km , to determine the best-fit high homopause eddy profile (HI), which is also displayed in Figure 6b.
[30] The nominal profile allows for more mixing in the middle atmosphere than previous models, with a larger eddy coefficient from $250-700 \mathrm{~km}$ (Figure 6c). The homopause level of 850 km is higher than the Yung et al. [1984], Toublanc et al. [1995], and Lara et al. [1996] profiles, although considerably lower than the Lara et al. [2002] model, which counteracts the result of a smaller methane upper atmosphere mole fraction from the higher homopause level by assuming a larger methane surface density.

## 4. Chemical Mechanisms

### 4.1. Hydrocarbons

[31] The formation of hydrocarbons begins with the photodissociation of $\mathrm{CH}_{4}$, which proceeds through the following channels:

$$
\begin{gather*}
\mathrm{CH}_{4}+h \nu \rightarrow \mathrm{CH}_{3}+\mathrm{H}  \tag{J4a}\\
\rightarrow{ }^{1} \mathrm{CH}_{2}+\mathrm{H}_{2} \\
\rightarrow{ }^{1} \mathrm{CH}_{2}+2 \mathrm{H}
\end{gather*}
$$

Figure 6. a) Randomly generated eddy diffusion profiles used to determine best fitting profile to constituent observations. b) Plots of tested eddy diffusion profiles nominal profile (solid line), Steiner and Bauer [1990] profile (dotted line), the best-fit high homopause profile (short dashed line), and the Lara et al. [2002] profile (long dashed line). Also included in the methane molecular diffusion coefficient profile c) Eddy diffusion profiles from various photochemical models - nominal profile (solid line), Yung et al. [1984] profile (dotted line), Toublanc et al. [1995] profile (short dashed line), Lara et al. [1996] profile (long dashed line), and Lara et al. [2002] profile (dot dashed line).

$$
\begin{equation*}
\rightarrow{ }^{3} \mathrm{CH}_{2}+2 \mathrm{H} \tag{J4d}
\end{equation*}
$$

$$
\begin{equation*}
\rightarrow \mathrm{CH}+\mathrm{H}_{2}+\mathrm{H} . \tag{J4e}
\end{equation*}
$$

The branching ratios for this process, particularly at Lyman $\alpha$, which accounts for $75 \%$ of methane photodissociation above 700 km , are still unsettled. Toublanc et al. [1995] used the Mordaunt et al. [1993] model 1 scheme, which
places half of methane dissociation into (J4a) while splitting the other half between (J4b) and (J4d), and Lara et al. [1996] chose the Mordaunt et al. [1993] model 2 scheme, splitting methane dissociation into (J4a) and (J4e). The scheme adopted for this model is the Romani [1996] scheme where the quantum yields at Lyman $\alpha$ are as follows: $\mathrm{q}(\mathrm{J} 4 \mathrm{a})=0.41, \mathrm{q}(\mathrm{J} 4 \mathrm{~b})=0.28, \mathrm{q}(\mathrm{J} 4 \mathrm{c})=0.0, \mathrm{q}(\mathrm{J} 4 \mathrm{~d})=0.21$, $\mathrm{q}(\mathrm{J} 4 \mathrm{e})=0.10$. At wavelengths other than Lyman $\alpha$, methane is assumed to dissociate into the (J4a) channel. Wilson and Atreya [2000b] examined and compared these methane photolytic schemes along with that provided by Smith and Raulin [1999] and determined that there was little impact in the distribution of $\mathrm{C}_{2}$-hydrocarbons, while there was considerable difference in the profiles of the $\mathrm{C}_{3} \mathrm{H}_{4}$ isomers and $\mathrm{C}_{3} \mathrm{H}_{6}$, mainly arising from the differences in CH yield among the schemes. The progression of hydrocarbon chemistry follows with reactions involving the radicals produced from methane dissociation.
[32] Ethylene is created in the upper atmosphere through two different addition/decomposition mechanisms - radical/ radical association

$$
\begin{equation*}
{ }^{3} \mathrm{CH}_{2}+\mathrm{CH}_{3} \rightarrow \mathrm{C}_{2} \mathrm{H}_{4}+\mathrm{H} \tag{R12}
\end{equation*}
$$

and the CH -insertion-H-elimination process involving methane

$$
\begin{equation*}
\mathrm{CH}+\mathrm{CH}_{4} \rightarrow \mathrm{C}_{2} \mathrm{H}_{4}+\mathrm{H} \tag{R5}
\end{equation*}
$$

to yield the net reaction $2 \mathrm{CH}_{4} \rightarrow \mathrm{C}_{2} \mathrm{H}_{4}+\mathrm{H}_{2}+2 \mathrm{H}$, as well as through ion chemistry in the scheme

$$
\begin{gather*}
\mathrm{N}_{2}+h \nu \rightarrow \mathrm{~N}_{2}^{+}+e^{-} \\
\mathrm{CH}_{4}+\mathrm{N}_{2}^{+} \rightarrow \mathrm{CH}_{3}^{+}+\mathrm{N}_{2}+\mathrm{H} \\
\mathrm{CH}_{4}+\mathrm{CH}_{3}^{+} \rightarrow \mathrm{C}_{2} \mathrm{H}_{5}^{+}+\mathrm{H}_{2} \\
\mathrm{HCN}+\mathrm{C}_{2} \mathrm{H}_{5}^{+} \rightarrow \mathrm{H}_{2} \mathrm{CN}^{+}+\mathrm{C}_{2} \mathrm{H}_{4}  \tag{S1}\\
e^{-}+\mathrm{H}_{2} \mathrm{CN}^{+} \rightarrow \mathrm{HCN}^{+\mathrm{H}} \\
\hline 2 \mathrm{CH}_{4} \rightarrow \mathrm{C}_{2} \mathrm{H}_{4}+\mathrm{H}_{2}+2 \mathrm{H}
\end{gather*}
$$

The ion contribution through (S1) controls ethylene production near the model-calculated ionospheric peak at 1060 km . However, the peak of ethylene production corresponds with the peak of methane dissociation near 800 km , controlled by processes (R12) and (R5) which accounts for $56 \%$ and $42 \%$, respectively, of ethylene production above 600 km [Wilson and Atreya, 2000b]. Once ethylene is formed, it serves as the major source of acetylene above 500 km through photolysis (J7), responsible for $75 \%$ of the total acetylene column production rate above 500 km . This differs from the Toublanc et al. [1995] and Yung et al. [1984] models where recombination of methylene radicals plays a larger role due to the authors' choice of methane photolytic scheme and the larger ${ }^{3} \mathrm{CH}_{2}$ recombination rate coefficient. Most of this acetylene is diffused into the lower atmosphere where it is polymerized to form higher-order hydrocarbons (e.g., $\mathrm{C}_{4} \mathrm{H}_{2}$ )

$$
\begin{gather*}
\mathrm{C}_{2} \mathrm{H}_{2}+h \nu \rightarrow \mathrm{C}_{2} \mathrm{H}+\mathrm{H} \\
\mathrm{C}_{2} \mathrm{H}+\mathrm{C}_{2} \mathrm{H}_{2} \rightarrow \mathrm{C}_{4} \mathrm{H}_{2}+\mathrm{H}  \tag{S2}\\
\hline 2 \mathrm{C}_{2} \mathrm{H}_{2} \rightarrow \mathrm{C}_{4} \mathrm{H}_{2}+2 \mathrm{H}
\end{gather*}
$$

$$

and more prominently in the lower atmosphere through

$$
\begin{gather*}
2 \mathrm{CH}_{4} \rightarrow \mathrm{C}_{2} \mathrm{H}_{4}+2 \mathrm{H}+\mathrm{H}_{2} \\
\mathrm{CH}_{4} \rightarrow \mathrm{CH}_{3}+\mathrm{H} \\
\mathrm{C}_{2} \mathrm{H}_{4}+h \nu \rightarrow \mathrm{C}_{2} \mathrm{H}_{2}+\mathrm{H}_{2} \\
\mathrm{C}_{2} \mathrm{H}_{2}+\mathrm{H} \xrightarrow{M} \mathrm{C}_{2} \mathrm{H}_{3}  \tag{S13}\\
\mathrm{C}_{2} \mathrm{H}_{3}+\mathrm{CH}_{3} \xrightarrow{\mathrm{M}} \mathrm{C}_{3} \mathrm{H}_{6} \\
\hline 3 \mathrm{CH}_{4} \rightarrow \mathrm{C}_{3} \mathrm{H}_{6}+2 \mathrm{H}_{2}+2 \mathrm{H}
\end{gather*}
$$

[35] Heavier hydrocarbons may also be formed in Titan's atmosphere - among the most prominent, benzene. Wilson et al. [2003] explored possible mechanisms for benzene formation, supported by the tentative detection of $\mathrm{C}_{6} \mathrm{H}_{6}$ by Coustenis et al. [2003]. Benzene in the lower stratosphere is primarily formed through the scheme
(S14)

$$
\begin{gather*}
4\left(\mathrm{C}_{2} \mathrm{H}_{2}+\mathrm{H} \xrightarrow{\mathrm{M}} \mathrm{C}_{2} \mathrm{H}_{3}\right) \\
2\left(\mathrm{C}_{2} \mathrm{H}_{3}+\mathrm{C}_{2} \mathrm{H}_{3} \xrightarrow{\mathrm{M}} \mathrm{C}_{4} \mathrm{H}_{6}\right) \\
2\left(\mathrm{C}_{4} \mathrm{H}_{6}+h \nu \rightarrow \mathrm{C}_{3} \mathrm{H}_{3}+\mathrm{CH}_{3}\right) \\
\mathrm{CH}_{3}+\mathrm{CH}_{3} \xrightarrow{\mathrm{M}} \mathrm{C}_{2} \mathrm{H}_{6} \\
\mathrm{C}_{3} \mathrm{H}_{3}+\mathrm{C}_{3} \mathrm{H}_{3} \xrightarrow{\mathrm{M}} n-\mathrm{C}_{6} \mathrm{H}_{6}  \tag{S18}\\
n-\mathrm{C}_{6} \mathrm{H}_{6}+\mathrm{H} \rightarrow \mathrm{C}_{6} \mathrm{H}_{6}+\mathrm{H} \\
\hline 4 \mathrm{C}_{2} \mathrm{H}_{2}+4 \mathrm{H} \rightarrow \mathrm{C}_{6} \mathrm{H}_{6}+\mathrm{C}_{2} \mathrm{H}_{6}
\end{gather*}
$$

with (S16) accounting for $60 \%$ of non-recycled HCN in the atmosphere. HCN is then diffused down into the lower atmosphere, providing the major source of HCN in this region, evident by an HCN flux of $3.4 \times 10^{8} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ at 600 km , where it undergoes recycling mechanisms, commenced through photolysis and H -addition

$$
\begin{gather*}
\mathrm{HCN}+h \nu \rightarrow \mathrm{CN}+\mathrm{H} \\
\frac{\mathrm{CN}+\mathrm{CH}_{4} \rightarrow \mathrm{HCN}+\mathrm{CH}_{3}}{\mathrm{CH}_{4} \rightarrow \mathrm{CH}_{3}+\mathrm{H}} \tag{S19}
\end{gather*}
$$

providing a minor pathway.

### 4.2. Nitriles

[36] Nitrogen, the predominant molecule in Titan's atmosphere, is largely chemically inert. The primary manner in

$$
\begin{gather*}
\mathrm{N}_{2}+e^{-} \rightarrow \mathrm{N}^{+}+\mathrm{N}^{4 \mathrm{~s}, 2 \mathrm{~d}}+2 e^{-} \\
\mathrm{CH}_{4}+\mathrm{N}^{+} \rightarrow \mathrm{H}_{2} \mathrm{CN}^{+}+\mathrm{H}_{2} \\
\frac{e^{-}+\mathrm{H}_{2} \mathrm{CN}^{+} \rightarrow \mathrm{HCN}+\mathrm{H}}{\mathrm{~N}_{2}+\mathrm{CH}_{4} \rightarrow \mathrm{HCN}+\mathrm{N}+\mathrm{H}_{2}+\mathrm{H}} \tag{S17}
\end{gather*}
$$

and photoionization

$$
\begin{gathered}
\mathrm{N}_{2}+h \nu \rightarrow \mathrm{~N}^{+}+\mathrm{N}^{2 \mathrm{~d}}+e^{-} \\
\mathrm{CH}_{4}+\mathrm{N}^{+} \rightarrow \mathrm{H}_{2} \mathrm{CN}^{+}+\mathrm{H}_{2} \\
\mathrm{~N}^{2 \mathrm{~d}}+\mathrm{C}_{2} \mathrm{H}_{4} \rightarrow \mathrm{CH}_{3} \mathrm{CN}+\mathrm{H} \\
\mathrm{CH}_{3} \mathrm{CN}+\mathrm{H}_{2} \mathrm{CN}^{+} \rightarrow \mathrm{CH}_{3} \mathrm{CNH}^{+}+\mathrm{HCN} \\
\mathrm{CH}_{4}+\mathrm{C}_{2} \mathrm{H}_{4} \rightarrow \mathrm{HCN}+\mathrm{H}_{2}+\mathrm{H}+\mathrm{CH}_{3} \mathrm{CNH}^{+}
\end{gathered}+e^{-} .
$$

which nitrogen is involved in chemistry is through dissociation via both photons and electrons. Nitrogen is photodissociated mainly due to radiation in the $800-1000 \AA$ region. Zipf and McLaughlin [1978] and Zipf et al. [1980] have determined the yields of nitrogen atoms from this process to be approximately $50 \%$ for ground-state $\mathrm{N}^{4 \mathrm{~s}}$ and $30-40 \%$ and $10-20 \%$ for excited states $\mathrm{N}^{2 \mathrm{~d}}$ and $\mathrm{N}^{2 \mathrm{p}}$, respectively. However, Zipf et al. [1980] found that $\mathrm{N}^{2 \text { p }}$ atoms are rapidly de-excited to the $\mathrm{N}^{2 \mathrm{~d}}$ state. Therefore $\mathrm{N}^{4 \mathrm{~s}}$ and $\mathrm{N}^{2 \mathrm{~d}}$ are assumed to adopt a quantum yield of 0.5 each from $\mathrm{N}_{2}$ photolysis. Nitrogen also undergoes electronimpact dissociation, with quantum yields determined by Zipf et al. [1980] and Itikawa et al. [1986].
[37] Nitrogen atoms combine with hydrocarbons to form an assortment of nitrile neutrals and ions in the upper atmosphere, as shown in Figure 8. The flux of $\mathrm{N}^{4 \mathrm{~s}}$ atoms combines with methane photolytic product, $\mathrm{CH}_{3}$, to form the basis of nitrile chemistry-HCN. HCN is formed through photodissociation

$$
\begin{gather*}
0.5\left(\mathrm{~N}_{2}+h \nu \rightarrow \mathrm{~N}^{4 s}+\mathrm{N}^{4 s}\right) \\
\mathrm{CH}_{4}+h \nu \rightarrow \mathrm{CH}_{3}+\mathrm{H} \\
\mathrm{~N}^{4 s}+\mathrm{CH}_{3} \rightarrow \mathrm{H}_{2} \mathrm{CN}+\mathrm{H}  \tag{S16}\\
\mathrm{H}_{2} \mathrm{CN}+\mathrm{H} \rightarrow \mathrm{HCN}+\mathrm{H}_{2} \\
.5 \mathrm{~N}_{2}+\mathrm{CH}_{4} \rightarrow \mathrm{HCN}+\mathrm{H}_{2}+\mathrm{H}
\end{gather*}
$$

18) 

electron impact processes

$$
\begin{gather*}
\mathrm{HCN}+\mathrm{H} \xrightarrow{\mathrm{M}} \mathrm{H}_{2} \mathrm{CN} \\
\frac{\mathrm{H}_{2} \mathrm{CN}+\mathrm{H} \rightarrow \mathrm{HCN}+\mathrm{H}_{2}}{\mathrm{H}+\mathrm{H} \rightarrow \mathrm{H}_{2}} . \tag{S20}
\end{gather*}
$$

Figure 8. Schematic of Titan nitrile chemistry. Stable species and primary reactions are shown in bold, with ions shown in rounded rectangles.
[38] $\mathrm{HC}_{3} \mathrm{~N}$ is produced primarily through the addition of the photolytic product CN and acetylene

$$
\begin{gather*}
\mathrm{HCN}+h \nu \rightarrow \mathrm{CN}+\mathrm{H} \\
\frac{\mathrm{CN}+\mathrm{C}_{2} \mathrm{H}_{2} \rightarrow \mathrm{HC}_{3} \mathrm{~N}+\mathrm{H}}{\mathrm{HCN}+\mathrm{C}_{2} \mathrm{H}_{2} \rightarrow \mathrm{HC}_{3} \mathrm{~N}+\mathrm{H}} . \tag{S21}
\end{gather*}
$$

[39] $\mathrm{C}_{4} \mathrm{~N}_{2}$ can also be formed through CN -insertion, as studied by Halpern et al. [1989]

$$
\begin{equation*}
\mathrm{CN}+\mathrm{HC}_{3} \mathrm{~N} \rightarrow \mathrm{C}_{4} \mathrm{~N}_{2}+\mathrm{H} \tag{R149}
\end{equation*}
$$

Yung [1987] proposed another mechanism for the formation of $\mathrm{C}_{4} \mathrm{~N}_{2}$ as well as $\mathrm{C}_{2} \mathrm{~N}_{2}$ through the action of the CHCN radical in the reactions

$$
\begin{equation*}
\mathrm{CHCN}+\mathrm{CHCN} \rightarrow \mathrm{C}_{4} \mathrm{~N}_{2}+\mathrm{H}_{2} \tag{R161}
\end{equation*}
$$

$$
\begin{equation*}
\mathrm{CHCN}+\mathrm{N}^{4 \mathrm{~s}} \rightarrow \mathrm{C}_{2} \mathrm{~N}_{2}+\mathrm{H} \tag{R160}
\end{equation*}
$$

Considering estimations by Yung [1987] for (R161), the main source of dicyanoacetylene is the scheme

$$
\begin{gather*}
\mathrm{N}_{2}+h \nu \rightarrow 2 \mathrm{~N}^{2 \mathrm{~d}} \\
2\left[\mathrm{~N}^{2 \mathrm{~d}}+\mathrm{C}_{2} \mathrm{H}_{2} \rightarrow \mathrm{CHCN}+\mathrm{H}\right]  \tag{S22}\\
\mathrm{CHCN}+\mathrm{CHCN} \rightarrow \mathrm{C}_{4} \mathrm{~N}_{2}+\mathrm{H}_{2} \\
\mathrm{~N}_{2}+2 \mathrm{C}_{2} \mathrm{H}_{2} \rightarrow \mathrm{C}_{4} \mathrm{~N}_{2}+2 \mathrm{H}+\mathrm{H}_{2}
\end{gather*}
$$

responsible for $98 \%$ of $\mathrm{C}_{4} \mathrm{~N}_{2}$ production throughout Titan's atmosphere. Likewise, $\mathrm{C}_{2} \mathrm{~N}_{2}$ is produced through the scheme

$$
\begin{gathered}
\mathrm{N}_{2}+h \nu \rightarrow \mathrm{~N}^{4 \mathrm{~s}}+\mathrm{N}^{2 \mathrm{~d}} \\
\mathrm{~N}^{2 \mathrm{~d}}+\mathrm{C}_{2} \mathrm{H}_{2} \rightarrow \mathrm{CHCN}+\mathrm{H} \\
\mathrm{~N}^{4 \mathrm{~s}}+\mathrm{CHCN} \rightarrow \mathrm{C}_{2} \mathrm{~N}_{2}+\mathrm{H}_{2} \\
\hline \mathrm{~N}_{2}+\mathrm{C}_{2} \mathrm{H}_{2} \rightarrow \mathrm{C}_{2} \mathrm{~N}_{2}+2 \mathrm{H}
\end{gathered},
$$

responsible for virtually all of $\mathrm{C}_{2} \mathrm{~N}_{2}$ production. Reactions with $\mathrm{CH}_{3}$ and $\mathrm{H}_{2} \mathrm{CN}$, to produce HCN , severely limit the availability of $\mathrm{N}^{4 \mathrm{~s}}$ atoms, giving a preference for CHCN to produce $\mathrm{C}_{4} \mathrm{~N}_{2}$ in the upper atmosphere.
[40] In the upper atmosphere, $\mathrm{C}_{2} \mathrm{H}_{3} \mathrm{CN}$ production follows along the same procedure as (S19),

$$
\begin{gather*}
\mathrm{HCN}+h \nu \rightarrow \mathrm{CN}+\mathrm{H} \\
\frac{\mathrm{CN}+\mathrm{C}_{2} \mathrm{H}_{4} \rightarrow \mathrm{C}_{2} \mathrm{H}_{3} \mathrm{CN}+\mathrm{H}}{\mathrm{HCN}+\mathrm{C}_{2} \mathrm{H}_{4} \rightarrow \mathrm{C}_{2} \mathrm{H}_{3} \mathrm{CN}+2 \mathrm{H}}, \tag{S24}
\end{gather*}
$$

while in the lower atmosphere, $\mathrm{C}_{2} \mathrm{H}_{3} \mathrm{CN}$ is produced through

$$
\begin{gather*}
\mathrm{C}_{2} \mathrm{H}_{2}+\mathrm{H} \xrightarrow{\mathrm{M}} \mathrm{C}_{2} \mathrm{H}_{3} \\
\mathrm{HCN}+\mathrm{C}_{2} \mathrm{H}_{3} \rightarrow \mathrm{C}_{2} \mathrm{H}_{3} \mathrm{CN}+\mathrm{H} \tag{S25}
\end{gather*} .
$$

### 4.3. Oxygen Species

[41] Stratospheric measurements of CO [e.g., Gurwell and Muhleman, 2000], $\mathrm{CO}_{2}$ [Coustenis et al., 1989], and $\mathrm{H}_{2} \mathrm{O}$ [Coustenis et al., 1998] have indicated the presence of oxygen chemistry in the atmosphere of Titan. A likely contributor to this oxygen inventory is an influx of micrometeorites into the atmosphere, providing a source of $\mathrm{H}_{2} \mathrm{O}$ molecules. Primarily, $\mathrm{H}_{2} \mathrm{O}$ molecules undergo UV photolysis. The formation of hydroxyl radicals through $\mathrm{H}_{2} \mathrm{O}$
photodissociation comprises $60 \%$ of $\mathrm{H}_{2} \mathrm{O}$ destruction in Titan's atmosphere. Some of the OH radicals serve to recycle $\mathrm{H}_{2} \mathrm{O}$. In fact, $54 \%$ of $\mathrm{H}_{2} \mathrm{O}$ destruction is recycled back to $\mathrm{H}_{2} \mathrm{O}$, mainly through charged-particle catalysis,

$$
\begin{gather*}
\mathrm{N}_{2}+h \nu \rightarrow \mathrm{~N}_{2}^{+}+e^{-} \\
\mathrm{N}_{2}^{+}+\mathrm{H}_{2} \mathrm{O} \rightarrow \mathrm{H}_{2} \mathrm{O}^{+}+\mathrm{N}_{2} \\
\mathrm{H}_{2} \mathrm{O}^{+}+\mathrm{CH}_{4} \rightarrow \mathrm{H}_{3} \mathrm{O}^{+}+\mathrm{CH}_{3}  \tag{S26}\\
\mathrm{H}_{3} \mathrm{O}^{+}+\mathrm{HCN} \rightarrow \mathrm{H}_{2} \mathrm{CN}^{+}+\mathrm{H}_{2} \mathrm{O} \\
\mathrm{CH}_{4}+\mathrm{HCN} \rightarrow \mathrm{H}_{2} \mathrm{CN}^{+}+\mathrm{CH}_{3}+e^{-}
\end{gather*}
$$

$$
\begin{gathered}
\mathrm{N}_{2}+h \nu \rightarrow \mathrm{~N}_{2}^{+}+e^{-} \\
\mathrm{N}_{2}^{+}+\mathrm{C}_{2} \mathrm{H}_{2} \rightarrow \mathrm{~N}_{2} \mathrm{H}^{+}+\mathrm{C}_{2} \mathrm{H} \\
\mathrm{~N}_{2} \mathrm{H}^{+}+\mathrm{H}_{2} \mathrm{O} \rightarrow \mathrm{H}_{3} \mathrm{O}^{+}+\mathrm{N}_{2} \\
\mathrm{H}_{3} \mathrm{O}^{+}+\mathrm{HCN} \rightarrow \mathrm{H}_{2} \mathrm{CN}^{+}+\mathrm{H}_{2} \mathrm{O} \\
\mathrm{CH}+\mathrm{H}_{4}+\mathrm{HCN} \rightarrow \mathrm{H}_{2} \mathrm{CN}^{+}+\mathrm{CH}_{3}+e^{-}
\end{gathered}
$$

through the reversibility of methylene-water addition
(R214a)

$$
\begin{aligned}
& { }^{1} \mathrm{CH}_{2}+\mathrm{H}_{2} \mathrm{O} \rightarrow \mathrm{CH}_{3}+\mathrm{OH} \\
& \mathrm{CH}_{3}+\mathrm{OH} \rightarrow \mathrm{H}_{2} \mathrm{O}+{ }^{1} \mathrm{CH}_{2},
\end{aligned}
$$

and through

$$
\begin{gather*}
\mathrm{H}_{2} \mathrm{O}+h \nu \rightarrow \mathrm{OH}+\mathrm{H} \\
\mathrm{OH}+\mathrm{CH}_{4} \rightarrow \mathrm{H}_{2} \mathrm{O}+\mathrm{CH}_{3}  \tag{S28}\\
\mathrm{CH}_{4} \rightarrow \mathrm{CH}_{3}+\mathrm{H}
\end{gather*} .
$$

The main destiny of OH radicals that are not recycled back to $\mathrm{H}_{2} \mathrm{O}$ is the formation of $\mathrm{CO}_{2}$ through reaction with primordial CO,

$$
\begin{equation*}
\mathrm{CO}+\mathrm{OH} \rightarrow \mathrm{CO}_{2}+\mathrm{H} . \tag{R219}
\end{equation*}
$$

[42] CO is engaged in chemistry mainly in the lower atmosphere, where it produces oxygenated compounds through pressure-dependent reactions

$$
\begin{equation*}
\mathrm{CO}+{ }^{3} \mathrm{CH}_{2} \xrightarrow{\mathrm{M}} \mathrm{CH}_{2} \mathrm{CO} \tag{R217}
\end{equation*}
$$

and

$$
\begin{gather*}
2(\mathrm{CO}+\mathrm{H} \xrightarrow{\mathrm{M}} \mathrm{HCO}) \\
\frac{\mathrm{HCO}+\mathrm{HCO} \rightarrow \mathrm{H}_{2} \mathrm{CO}+\mathrm{CO}}{\mathrm{CO}+2 \mathrm{H} \rightarrow \mathrm{H}_{2} \mathrm{CO}} \tag{S29}
\end{gather*}
$$

However, photolysis of these compounds simply leads to CO recycling, the dominant mechanism in Titan oxygen chemistry.

### 4.4. Ion Chemistry

[43] Ion chemistry in Titan's atmosphere commences with the ionization of molecular nitrogen. Nitrogen is ionized by solar photons below $796 \AA$ and by electron impact. These sources provide $\mathrm{N}_{2}^{+}$and $\mathrm{N}^{+}$ions that readily react with neutrals to form larger ions. Likewise, the abundance of $\mathrm{CH}_{4}$ in the upper atmosphere makes its ionization an
important early process in the formation of the ionosphere. Methane is ionized by photons and electrons producing a number of hydrocarbon and hydrogen ions.
[44] The formation of most of the ions in Titan's ionosphere begin with the mechanism

$$
\begin{gather*}
\mathrm{N}_{2}+h \nu \rightarrow \mathrm{~N}_{2}^{+}+e^{-} \\
\mathrm{N}_{2}^{+}+\mathrm{CH}_{4} \rightarrow \mathrm{CH}_{3}^{+}+\mathrm{N}_{2}+\mathrm{H} \\
\mathrm{CH}_{3}^{+}+\mathrm{CH}_{4} \rightarrow \mathrm{C}_{2} \mathrm{H}_{5}^{+}+\mathrm{H}_{2}  \tag{S30}\\
\hline 2 \mathrm{CH}_{4} \rightarrow \mathrm{C}_{2} \mathrm{H}_{5}^{+}+\mathrm{H}_{2}+\mathrm{H}+e^{-}
\end{gather*}
$$

which serves to produce the abundant ion $\mathrm{C}_{2} \mathrm{H}_{5}^{+} . \mathrm{H}_{2} \mathrm{CN}^{+}$, found to be the major ion in the Keller et al. [1992] and Banaszkiewicz et al. [2000] models, is produced through

$$
\begin{gather*}
2 \mathrm{CH}_{4} \rightarrow \mathrm{C}_{2} \mathrm{H}_{5}^{+}+\mathrm{H}_{2}+\mathrm{H}+e^{-} \\
\frac{\mathrm{C}_{2} \mathrm{H}_{5}^{+}+\mathrm{HCN} \rightarrow \mathrm{H}_{2} \mathrm{CN}^{+}+\mathrm{C}_{2} \mathrm{H}_{4}}{}  \tag{S31}\\
2 \mathrm{CH}_{4}+\mathrm{HCN}_{\mathrm{HCN}}^{\mathrm{H}_{2} \mathrm{CN}^{+}+\mathrm{C}_{2} \mathrm{H}_{4}+\mathrm{H}_{2}+\mathrm{H}+e^{-}}
\end{gather*}
$$

and

$$
\begin{gather*}
\mathrm{N}_{2}+h \nu \rightarrow \mathrm{~N}_{2}^{+}+e^{-} \\
\mathrm{N}_{2}^{+}+\mathrm{H}_{2} \rightarrow \mathrm{~N}_{2} \mathrm{H}^{+}+\mathrm{H} \\
\mathrm{~N}_{2} \mathrm{H}^{+}+\mathrm{CH}_{4} \rightarrow \mathrm{CH}_{5}^{+}+\mathrm{N}_{2}  \tag{S32}\\
\mathrm{CH}_{5}^{+}+\mathrm{HCN} \rightarrow \mathrm{H}_{2} \mathrm{CN}^{+}+\mathrm{CH}_{4} \\
\hline \mathrm{HCN}+\mathrm{H}_{2} \rightarrow \mathrm{H}_{2} \mathrm{CN}^{+}+\mathrm{H}+e^{-}
\end{gather*}
$$

where ( S 31 ) is responsible for $78 \%$ of $\mathrm{H}_{2} \mathrm{CN}^{+}$production and (S32) accounts for $10 \%$. As indicated previously, the main function of $\mathrm{H}_{2} \mathrm{CN}^{+}$ions is the formation of HCN through electron recombination (R349) and through reactions (R347) and scheme ( S 18 ), while $\mathrm{C}_{2} \mathrm{H}_{5}^{+}$serves to convert nitriles to hydrocarbons through (S31).

## 5. Results and Discussion

### 5.1. Sensitivity to Eddy Diffusion and Methane Abundance

[45] A test of the accuracy of a photochemical model is comparison with observations of constituent abundances. However, exactly what is being considered when dealing with observations must be taken into account. The large error bars associated with the Vervack et al. (submitted manuscript, 2003) UVS reanalysis and the questions about the $\mathrm{CH}_{4}$ and $\mathrm{C}_{2} \mathrm{H}_{2}$ observations that affect the retrieval of other species, as well, have been pointed out in section 3.5.2. However, the absence of other observations of constituent densities in Titan's upper atmosphere, with the exception of $\mathrm{CH}_{4}$ and $\mathrm{C}_{2} \mathrm{H}_{2}$, and the difficulty in reconciling Titan chemistry with the Smith et al. [1982] $>825 \mathrm{~km} \mathrm{C}_{2} \mathrm{H}_{2}$ observation suggests the use of the Vervack non- $\mathrm{CH}_{4}$ retrievals as a preliminary guide to how Titan's constituents might be distributed in the upper atmosphere. Furthermore, many of the existing observations in the stratosphere (e.g., IRIS) are determined assuming a uniform mole fraction profile, which is not realistic for chemically active constituents, affecting the abundances derived. For instance, Coustenis et al. [1989] derived a $\mathrm{CO}_{2}$ mole fraction of $1.4_{-0.5}^{+0.3} \times 10^{-8}$ at 105 km , the altitude where the contribution function of $\mathrm{CO}_{2}$ peaks. However, as dictated by the contribution function, the IRIS instrument received signal
contribution from layers above and below this layer. Consequently, an uncertainty of $+55,-30 \mathrm{~km}$ is included with this result, associated with the region where the contribution function is greater than half of the peak value. The authors were able to fit the obtained spectra with a $\mathrm{CO}_{2}$ mole fraction profile that reaches $1.4 \times 10^{-8}$ at $\sim 180 \mathrm{~km}$ and decreases to $5 \times 10^{-9}$ at 105 km , outside the range of values indicated at the contribution peak assuming a uniform mole fraction profile. A similar case is found for $\mathrm{H}_{2} \mathrm{O}$ as the stratospheric value of $4 \times 10^{-10}$ is 20 times smaller than the value of the best-fitting $\mathrm{H}_{2} \mathrm{O}$ mole fraction profile, provided by Lara et al. [1996], at the peak of the contribution function for the observation [Coustenis et al., 1998]. Thus the assumption of a uniform profile must be kept in mind when comparing model results to observations.
[46] To demonstrate the effect of the eddy diffusion coefficient on the distribution of constituents, mole fraction profiles of key constituents for the eddy diffusion profiles demonstrated in Figure 6 are displayed in Figures 9 and 10. Figure 9 shows the results for $\mathrm{CH}_{4}$ and HCN , key constituents used as guides in obtaining the eddy coefficient along with the observations referred to in section 3.5.2. The Vervack et al. (submitted manuscript, 2003) and Vervack [1997] UVS reanalysis observations displayed represent the extremes of both ingress and egress results, converted to mole fractions on the basis of the nominal total number density profile of this model.
[47] The nominal $\mathrm{CH}_{4}$ profile fits the Smith et al. [1982] 1125 km observation along with the Strobel et al. [1992] 1400 km observation and the Vervack et al. (submitted manuscript, 2003) observations up to $\sim 1000 \mathrm{~km}$. SB approximates the upper limits of Smith et al. [1982] while HI matches Vervack et al. (submitted manuscript, 2003) up to higher levels but does not approach the Strobel et al. [1992] observation.
[48] For HCN the nominal profile fits the Tanguy et al. [1990] observations at 100 km and 200 km , as well as provides a good fit to the Coustenis et al. [1989] IRIS observations. Above 300 km , the nominal profile splits the divergent observations of Tanguy et al. [1990] and Hidayat et al. [1997] HI was generated to fit the Hidayat et al. [1997] HCN observations below 300 km as closely as possible, while simultaneously matching the $\mathrm{CH}_{4}$ Vervack et al. (submitted manuscript, 2003) observations up to 1000 km , but is unable to completely match the HCN observations below 200 km . On the other hand, SB clearly overpredicts the HCN abundance in the lower stratosphere.
[49] In the upper atmosphere, the nominal profile provides a reasonable fit to the Vervack [1997] reanalysis, below 800 km , in all cases with the exception of $\mathrm{C}_{2} \mathrm{H}_{2}$. The $\mathrm{C}_{2} \mathrm{H}_{2}$ nominal profile overpredicts acetylene abundance in relation to the Vervack [1997] results, consistent with the other photochemical models but on a lesser scale than the Yung et al. [1984] or Toublanc et al. [1995] models. Vervack et al. (submitted manuscript, 2003) provide reanalysis profiles assuming $\mathrm{C}_{2} \mathrm{H}_{2}$ to be the only absorbing species that exceeds the nominal profile. Furthermore, it is difficult to imagine a $\mathrm{C}_{2} \mathrm{H}_{2}$ profile with a shape that fits both the stratospheric and nominal upper atmosphere observations, simultaneously, absent a significant localized sink around to $10^{-1}-10^{-2}$ millibar region. This raises the possibility that more absorption should be ascribed to

Figure 9. a) $\mathrm{CH}_{4}$ and b) HCN profiles using the nominal eddy diffusion profile (NOM, solid line), Steiner and Bauer [1990] profile (SB, dotted line), the high homopause profile (HI, short dashed), and the Lara et al. [2002] profile (NL, long dashed line). The group of horizontal lines represent the Vervack [1997] reanalysis of UVS observations. In a) the horizontal bars at 1000 km and 1130 km represent the Smith et al. [1982] observations, while the horizontal bar at 1400 km indicates the Strobel et al. [1992] Voyager UVS observations. In b) the solid horizontal lines in the lower portion of the plot shows the Hidayat et al. [1997] observations with the dotted lines representing the Tanguy et al. [1990] results, and the box represents the stratospheric Voyager IRIS observations including error bars in abundance and altitude.
$\mathrm{C}_{2} \mathrm{H}_{2}$ in the UVS reanalysis than their nominal observations suggest. Above 800 km , NOM falls off with respect to the Vervack [1997] observations for $\mathrm{C}_{4} \mathrm{H}_{2}$ and $\mathrm{HC}_{3} \mathrm{~N}$. However, these constituents have short lifetimes in this region of the atmosphere compared with a solar cycle and thus are sensitive to changes in the solar radiation output, as discussed in the next section, and assuming solar maximum conditions provides a better fit to this data. Furthermore, as Vervack [1997] points out, the uniformity in number density with respect to altitude for the $\mathrm{C}_{4} \mathrm{H}_{2}$ and $\mathrm{HC}_{3} \mathrm{~N}$ observations suggest that these species may not have been well-retrieved. Misassignment of $\mathrm{CH}_{4}$ absorption may have understated $\mathrm{CH}_{4}$ densities at high altitudes while overstating these species.
[50] The high homopause eddy diffusion profile limits the amount of methane in the upper atmosphere, resulting in

Figure 10. Constituent profiles using the nominal eddy diffusion profile (NOM, solid line), Steiner and Bauer [1990] profile (SB, dotted line), the high homopause profile (HI, short dashed), and the Lara et al. [2002] profile (NL, long dashed line). The boxes represent the stratospheric Voyager IRIS observations including error bars in abundance and altitude, while the horizontal lines represent the Vervack [1997] reanalysis of UVS observations.
less conversion to higher order hydrocarbons and, consequently, smaller hydrocarbon abundances. HI matches the $\mathrm{C}_{2} \mathrm{H}_{2}$ and $\mathrm{C}_{2} \mathrm{H}_{4}$ upper atmosphere observations well, but underpredicts for $\mathrm{C}_{2} \mathrm{H}_{6}, \mathrm{C}_{4} \mathrm{H}_{2}$ and $\mathrm{HC}_{3} \mathrm{~N}$. SB , on the other hand, provides reasonable predictions only for $\mathrm{HC}_{3} \mathrm{~N}$ and $\mathrm{C}_{2} \mathrm{H}_{6}$ above 700 km , according to the Vervack et al. (submitted manuscript, 2003) observations. The HI profile significantly underpredicts constituent abundances in the stratosphere, while SB matches IRIS observations only for the $\mathrm{C}_{2}$-hydrocarbons.
[51] Recently, Lara et al. [2002] reanalyzed this question of the eddy diffusion coefficient in relation to the methane density in the upper atmosphere. They proceeded by recalculating the methane density with an assumption of $\mathrm{CH}_{4}$ stratospheric mole fraction at $3.8 \%$, compared to the Lara et al. [1996] assumption of $1.7 \%$. This value assumes very high methane supersaturation in the troposphere, which according to Courtin et al. [1995], can be as high as $230 \%$. In contrast, the nominal model uses the results of Samuelson et al. [1997], which places the level of maxi-

Figure 11. Photodissociation coefficients of key species.
mum methane supersaturation at $1.48 \pm 0.11$, using a methodology that, according to the authors, avoids some of the sources of systematic error inherent in the Courtin et al. [1995] study. A methane supersaturation value of 1.37 yields of $\mathrm{CH}_{4}$ stratospheric mole fraction of $2.2 \%$. Nevertheless, with the large methane abundance, Lara et al. [2002] adopt an eddy diffusion profile (NL) that increases rapidly in the stratosphere and middle atmosphere, resulting in a high homopause level around 1000 km (Figure 6b). This profile with a $\mathrm{CH}_{4}$ stratospheric mole fraction of $3.8 \%$ was tested along with the nominal case. As Figure 9 shows, NL provides good agreement with the HCN infrared and microwave observations, which eliminates the necessity for a large sink for HCN to the haze due to polymerization, as promoted by Lara et al. [1999]. However, demonstrated by Figure 10, the NL case underpredicts hydrocarbons in the lower stratosphere, with the exception of $\mathrm{C}_{4} \mathrm{H}_{2} . \mathrm{C}_{3}$-hydrocarbons are especially diminished in the NL case, with a $\mathrm{CH}_{3} \mathrm{C}_{2} \mathrm{H}$ profile that is two orders of magnitude smaller and a $\mathrm{C}_{3} \mathrm{H}_{8}$ profile (not shown) that is an order of magnitude smaller than IRIS observations. In the upper atmosphere, the nominal case provides profiles more consistent with the UVS reanalysis than the NL case, as well.

### 5.2. Sensitivity to Solar Flux and Aerosol Structure

[52] The stable constituents in Titan's atmosphere are dissociated and ionized by solar photons and electrons that are transferred through the atmosphere. A comparison of Figure 11 and absorption cross sections will yield the deposition regions of different wavelength regions. $\mathrm{N}_{2}$, which is dissociated by EUV photons, undergoes attenuation in dissociation in the upper atmosphere, with $\mathrm{J}_{\mathrm{N}_{2}}$ having been reduced by an order of magnitude at 1000 km . Below 900 km , electron impact dominates $\mathrm{N}_{2}$ absorption as $\mathrm{J}_{\mathrm{N}_{2}}$ drops off at the base of the ionosphere at 720 km . Abundant species that undergo significant absorption of photons at $1000 \AA \leq \lambda \leq 1450 \AA$ experience dissociation attenuation around 800 km , as these photons are deposited through methane absorption. Deposition of UV radiation longer than $1450 \AA$ occurs lower in the atmosphere, at $200-300 \mathrm{~km}$, as a result of absorption by molecules such as $\mathrm{HCN}(\lambda \leq 1800 \AA)$ and $\mathrm{C}_{2} \mathrm{H}_{2}(\lambda \leq 2100 \AA)$ as well as by aerosols $(\lambda \geq 1800 \AA)$.
[53] During much of the upcoming Cassini-Huygens encounter with Titan, the Sun will undergo moderate solar activity, likely resulting in a reduced solar flux compared with what took place during the Voyager flybys. In Titan's atmosphere, constituents above 500 km are typically destroyed chemically within one solar cycle, while for certain stable constituents, like $\mathrm{C}_{4} \mathrm{H}_{2}$, their relatively short lifetimes may allow changes in solar output to affect their lower stratospheric abundances, as well. With this in mind, it is constructive to analyze the effect of variations in solar flux on the distribution of various key constituents in Titan's atmosphere. Figure 12 provides such a comparison, assuming solar fluxes in the FUV and NUV obtained by SOLSTICE for average solar maximum, solar moderate, and solar minimum conditions, with the corresponding EUV calculated fluxes for $(\mathrm{F} 10.7, \mathrm{~F} 10.7 \mathrm{~A})=(233$, 211.9), (130, 130), and (70, 70), respectively. The $\mathrm{C}_{2^{-}}$ hydrocarbons, which are more directly affected by methane and its dependence in the upper atmosphere on transport rather than chemistry, show little dependence on solar activity. However, nitriles like HCN and $\mathrm{HC}_{3} \mathrm{~N}$ show much more sensitivity in the upper atmosphere to solar output as HCN photolysis plays a considerably larger role with respect to transport than $\mathrm{CH}_{4}$ photolysis.
[54] In comparing the nominal dissociation coefficients with the photodissociation coefficients of Toublanc et al. [1995] and Lara et al. [1996] the most glaring differences reside in the lower 300 km . The nominal dissociation coefficients fall off much more rapidly than Lara et al. [1996] most likely due to differences in the treatment of aerosols. Solar radiation at wavelengths $1800 \AA \leq \lambda \leq$ $2100 \AA$ is relatively unattenuated in the Lara et al. [1996] model, reaching to lower regions, while those photons are deposited above 200 km in the nominal model due to $\mathrm{C}_{2} \mathrm{H}_{2}$ absorption and aerosol opacity. The assertion of significant opacity at these wavelengths is corroborated by the analysis of UV spectra by McGrath et al. [1998]. The Toublanc et al. [1995] photodissociation rates fall off more significantly than Lara et al. [1996] which used the Yung et al. [1984] parameterization of aerosol absorption, but less than the nominal case, probably a result of consideration of Mie haze particles. For instance, $\mathrm{J}_{\mathrm{C}_{2}} \mathrm{H}_{2}(100 \mathrm{~km}) / \mathrm{J}_{\mathrm{C}_{2}} \mathrm{H}_{2}(500 \mathrm{~km})=$ $1.0 \times 10^{-5}$ in the nominal model while Toublanc et al. [1995] and Lara et al. [1996] yield $4.8 \times 10^{-2}$ and $8.2 \times$ $10^{-3}$, respectively. Fractal particles are more opaque than Mie particles at short wavelengths [Rannou et al., 1995], limiting the penetration of radiation at deeper levels. However, aerosol opacities amount to a significant uncertainty affecting photodissociation coefficients, as Titan aerosol densities and optical constants are still not well understood. The effect of the type of aerosol particle considered is shown in Figure 13, which compares constituent mole fraction profiles from the nominal case with those assuming Mie opacities derived from Rannou et al. [1995]. In the Mie case more radiation is allowed to penetrate into the lower atmosphere, promoting greater formation of $\mathrm{CH}_{3}$ radical through catalytic dissociation of methane (S5) and increasing the levels of ethane and propane in the atmosphere. Furthermore, the smaller opacity provided by Mie particles longward of $1800 \AA$ results in much larger dissociation of $\mathrm{HC}_{3} \mathrm{~N}$ and $\mathrm{C}_{2} \mathrm{H}_{3} \mathrm{CN}$ molecules which significantly absorb in that wavelength region. The IRIS $\mathrm{HC}_{3} \mathrm{~N}$ upper limit of

Figure 12. Constituent profiles for average solar maximum (long dashed line), solar moderate (solid line), and solar minimum conditions (dotted line).
$1.5 \times 10^{-9}$ and the lack of observations of $\mathrm{C}_{2} \mathrm{H}_{3} \mathrm{CN}$ suggest that more absorption of these molecules takes place in the lower atmosphere than what is determined by the nominal profile. These factors along with the $\mathrm{C}_{3} \mathrm{H}_{8}$ Mie profile hint at possibly less aerosol opacity in Titan's stratosphere than what is considered in the nominal case.

### 5.3. Hydrocarbons

[55] Figure 10 shows that the model slightly underpredicts ethylene density in Titan's stratosphere. This issue is a
factor in the Toublanc et al. [1995] model, as well. Lara et al. [1996] assumed a boundary condition of $1.5 \times 10^{-7}$ to match IRIS observations, necessitating a flux of $7.0 \times$ $10^{7} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ from the surface, resulting from some surficial process (e.g., outgassing). The nominal model calculates a $\mathrm{C}_{2} \mathrm{H}_{4}$ net loss of $8.1 \times 10^{7} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ (Table 7), requiring a corresponding flux from the surface in order to maintain steady state equilibrium. Such a flux, which would not be cold-trapped as $\mathrm{C}_{2} \mathrm{H}_{4}$ does not condense at those abundances, is a viable mechanism to account for the IRIS obser-

Figure 13. Constituent profiles assuming fractal haze particles (solid line) and Mie haze particles (long dashed line). The boxes represent the stratospheric Voyager IRIS observations including error bars in abundance and altitude, while the horizontal lines represent the Vervack [1997] reanalysis of UVS observations. For HCN, the solid horizontal bars show the Hidayat et al. [1997] observations with the dotted bars representing the Tanguy et al. [1990] observations.
vations. Possible irradiation of hydrocarbon condensates on Titan's surface may also provide a source of $\mathrm{C}_{2} \mathrm{H}_{4}$ in the stratosphere.
[56] Canosa et al. [1997] measured the $\mathrm{CH}+\mathrm{CH}_{4}$ rate coefficient in a temperature range of $23-295 \mathrm{~K}$, but could
not positively identify products. Thermochemical and kinetic analysis indicate, however, that H -atom elimination is the most favored process [Canosa et al., 1997], yielding the $\mathrm{C}_{3} \mathrm{H}_{4}$ complex. With potential products $\mathrm{CH}_{3} \mathrm{C}_{2} \mathrm{H}$ and $\mathrm{CH}_{2} \mathrm{CCH}_{2}$ similarly exothermic, these isomers are assumed

|  | Production (P), <br> $\mathrm{cm}^{-2} \mathrm{~s}^{-1}$ | Loss $(\mathrm{L})$, <br> $\mathrm{cm}^{-2} \mathrm{~s}^{-1}$ | $\mathrm{P}-\mathrm{cm}^{-2} \mathrm{~L}^{-1}$ | Chemical Lifetime <br> at $300 \mathrm{~km}, \mathrm{~s}$ |
| :--- | :--- | :--- | ---: | :--- |
| Species $^{\mathrm{a}}$ |  |  |  |  |

in this model to have a branching ratio of 0.5 for this reaction. This mechanism for forming methylacetylene and allene is not considered in other Titan photochemical models. With this assumption, the $\mathrm{CH}_{3} \mathrm{C}_{2} \mathrm{H}$ profile shown in Figure 10 agrees well with observations as opposed to Toublanc et al. [1995], which is a factor of six too large or Lara et al. [1996], which is two orders of magnitude too small (Table 8).
[57] Notwithstanding the effect of aerosol opacity, the model-generated propane profile has a similar uniform shape in the homosphere as the Yung et al. [1984], Lara et al. [1996], and Lebonnois et al. [2001]. The Toublanc et al. [1995] $\mathrm{C}_{3} \mathrm{H}_{8}$ profile shape differs with propane peaking at 500 km , mainly a product of their chemical scheme which results in a $\mathrm{C}_{3} \mathrm{H}_{8}$ net production rate 15 times larger than the Lara et al. [1996] or our nominal rate. In our model, the $\mathrm{C}_{3} \mathrm{H}_{8}$ abundance is governed by the synthesis of ethyl and methyl radicals (R51b) above 140 km , and the self-reaction of $\mathrm{C}_{3} \mathrm{H}_{7}$ radicals (R81) below 140 km , which facilitates the recycling of propane in the stratosphere, via $\mathrm{H}_{2}$-elimination in propane photolysis ( J 15 a ) and subsequent hydrogen attachment (R72). The omission of this recycling mechanism in the Lara et al. [1996] scheme is responsible for their $\mathrm{C}_{3} \mathrm{H}_{8}$ fall-off above $100 \mathrm{~km} .89 \%$ of propane created is lost to condensation below 50 km .
[58] The diacetylene profile compares well with the IRIS observations while both Toublanc et al. [1995] and Lara et al. [1996] overpredict $\mathrm{C}_{4} \mathrm{H}_{2}$ abundance, by a factor of three and two, respectively, due to smaller eddy mixing in the stratosphere. The $\mathrm{C}_{4} \mathrm{H}_{2}$ profile shape compares similarly to the Lebonnois et al. [2001] $\mathrm{C}_{4} \mathrm{H}_{2}$ equatorial profile shape, although the nominal profile exhibits larger diacetylene densities in the stratosphere as a result of larger acetylene mixing ratios, compared to the Lebonnois et al. [2001] $\mathrm{C}_{2} \mathrm{H}_{2}$ equatorial profile. Diacetylene reacts with the photo-

Figure 14. Nominal constituent profiles for various hydrocarbon species along with atomic nitrogen, atomic hydrogen, and molecular hydrogen.
lytic products of $\mathrm{C}_{2} \mathrm{H}_{2}$ and $\mathrm{C}_{4} \mathrm{H}_{2}$ to form $\mathrm{C}_{6} \mathrm{H}_{2}$ and $\mathrm{C}_{8} \mathrm{H}_{2}$, whose profiles are shown in Figure 14. These processes may have implications in the formation of Titan haze between $500-800 \mathrm{~km}$.
[59] Wilson et al. [2003] suggested the possibility of benzene formation in Titan's atmosphere, corroborated by the tentative detection of benzene by the Infrared Space Observatory (ISO) [Coustenis et al., 2003]. The observation fit by a uniform mole fraction profile of $4 \pm 3 \times 10^{-10}$ was matched by a vertical profile of benzene from Wilson et al. [2003], multiplied by $3.0 \pm 0.5$, an upper-limit profile calculated assuming reaction rates for aromatic compounds that correspond to a temperature of 300 K . However, aerosol opacity was not considered in that calculation. Haze particles act to shield benzene from photodissociation, which extends as far as $2700 \AA$ [Pantos et al., 1978]. Figure 15 compares the nominal benzene profile from Wilson et al. [2003] with the present nominal profiles including aerosols and calculated with the nominal temperature profile, taken from Yelle et al. [1997], which ranges from 71 K at the tropopause to 175 K in the thermosphere. The present profile matches the ISO observation with a column density of $2.4 \times 10^{15} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ above 30 mbar , with a benzene mole fraction of $6.1 \times 10^{-10}$ at 110 km . The only other modeling study that covers benzene abundance on Titan is Lebonnois et al. [2002], which calculates a benzene mole fraction at least three orders of magnitude smaller at the observation altitude. Figure 15 also demonstrates the large dependence on solar flux for benzene
abundance in the upper atmosphere. Wilson and Atreya [2003] explored possible mechanisms for haze formation and suggested that aromatic compounds like benzene could be a source of Titan haze. Assuming this nominal benzene profile and that the mechanism for haze formation begins with the reactions

$$
\begin{align*}
& \mathrm{C}_{6} \mathrm{H}_{6}+\mathrm{C}_{2} \mathrm{H} \rightarrow \text { haze }  \tag{R115}\\
& \mathrm{C}_{6} \mathrm{H}_{5}+\mathrm{C}_{2} \mathrm{H}_{2} \rightarrow \text { haze }
\end{align*}
$$

the aromatic pathway provides a haze production rate of $9.5 \times 10^{6} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ or $3.2 \times 10^{-14} \mathrm{~g} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$, assuming a nucleation mass of 2000 amu [Richter and Howard, 2000], compared with $0.5-2 \times 10^{-14} \mathrm{~g} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ derived by microphysical models [McKay et al., 2001].
[60] An important uncertainty in modeling chemistry in outer planetary atmospheres is the methyl recombination rate. Methyl recombination serves as the primary loss mechanism for the chemically important methyl radical as well as the source of ethane production. However, until recently, rate measurements have only been taken as low as room temperature, with extrapolations down to lower temperatures yielding widely varying results [Atreya et al., 1999]. ISO observations of $\mathrm{CH}_{3}$ seem to indicate that the more widely used Slagle et al. [1988] rate expression is too low, perhaps by an order of magnitude. For this reason, we use a methyl recombination rate that is ten times that obtained with the Slagle et al. [1988] expression. Studies comparing hydrocarbon mixing ratio profiles using both the Slagle et al. [1988] rate and our rate indicate little difference in the ethane stratospheric profile and a factor a two increase in ethane density in the upper atmosphere with our rate [Wilson and Atreya, 2000a]. Recently, Cody et al. [2003] have measured methyl recombination at lower temperatures, obtaining results at as low as 155 K . These results find

Figure 15. Benzene profiles for average solar maximum (long dashed line), solar moderate (solid line), and solar minimum conditions (dotted line), along with the Wilson et al. [2003] nominal benzene profile (short dashed line). The box represents the ISO benzene observations including error bars in abundance and altitude.

Figure 16. Constituent profiles of various nitrile species including cosmic ray deposition (thick line) and no cosmic ray deposition (thin line).
methyl recombination to proceed at roughly 1.6 times the Slagle et al. [1988] rate at high pressures. However, these experiments were conducted with He as a bath gas, and the reaction may proceed faster with $\mathrm{N}_{2}$ as the background atmosphere as exhibited by the hydrogen atom recombination reaction, which proceeds $60 \%$ faster at 150 K with the Tsang and Hampson [1986] rate which uses an $\mathrm{N}_{2}$ bath gas, as opposed to the Baulch et al. [1992] rate which uses an $\mathrm{H}_{2}$ bath gas. Using the Cody et al. [2003] rate, the nominal ethane density in the upper atmosphere is reduced by $55 \%$ at 1100 km and reduced by $6 \%$ at 200 km , while the $\mathrm{CH}_{3}$ density is increased by $145 \%$ and $35 \%$, respectively, at those altitudes.

### 5.4. Nitriles

[61] Cosmic rays can play a substantial role in the formation of nitriles. Cosmic rays penetrate the atmosphere and dissociate nitrogen molecules (Figure 4b), producing N atoms that serve as a source for stratospheric nitriles, in particular, nitriles that are formed directly from N -atom addition. In addition, Molina-Cuberos et al. [2002] demonstrated that the possible formation of ion clusters in this region through high pressure reactions may be a source of stratospheric nitriles. The kinetics and identification of products of these reactions, however, are still to be determined. Figure 16 shows the profiles of several nitrile compounds with and without the inclusion of galactic cosmic rays. In particular, the stratospheric abundances of $\mathrm{C}_{2} \mathrm{~N}_{2}$ and $\mathrm{C}_{4} \mathrm{~N}_{2}$ are highly dependent on cosmic ray dissociation of nitrogen, through the schemes (S20) and (S21). Treatment of cosmic ray interaction through particle cascade, illustrated by Capone et al. [1983], may increase $\mathrm{C}_{2} \mathrm{~N}_{2}$ and $\mathrm{C}_{4} \mathrm{~N}_{2}$ densities in the lower atmosphere further.
[62] Lara et al. [1996] in order to explain the $\mathrm{CH}_{3} \mathrm{CN}$ observations announced by Bézard et al. [1993] propose a source provided by $\mathrm{CH}_{4}+\mathrm{CN}$ and $\mathrm{C}_{2} \mathrm{H}_{6}+\mathrm{CN}$. Previous studies [Hess et al., 1989; Yang et al., 1992b; Sims et al., 1993], however, give no indication of an acetonitrile channel, while Balla et al. [1991] point out that though the $\mathrm{CH}_{3} \mathrm{CN}$ channel is thermodynamically possible, their mea-
surements only indicate traces of $\mathrm{CH}_{3} \mathrm{CN}$. Nevertheless, Lara et al. assume a quantum yield for the production of 0.05 for $\mathrm{CH}_{4}+\mathrm{CN}$ and 0.035 for $\mathrm{C}_{2} \mathrm{H}_{6}+\mathrm{CN}$. The reaction $\mathrm{N}^{2 \mathrm{~d}}+\mathrm{C}_{2} \mathrm{H}_{4}$ was taken to proceed at a rate of $1.2 \times$ $10^{-12} \mathrm{~cm}^{-3} \mathrm{~s}^{-1}$ by Lellouch et al. [1994] in their Neptune model, on the basis of $\mathrm{N}^{2 \mathrm{~d}}$ quenching coefficients by Black et al. [1969]. They predicted the reaction to proceed in an insertion/abstraction manner, producing products NH and $\mathrm{C}_{2} \mathrm{H}_{3}$. This reaction was included in the Lara et al. model, while Toublanc et al. [1995] and Yung [1987] did not include this reaction. However, Sato et al. [1999] measured $\mathrm{N}^{2 \mathrm{~d}}+\mathrm{C}_{2} \mathrm{H}_{4}$ down to 230 K and obtained a rate of $2.6 \times$ $10^{-11} \mathrm{~cm}^{-3} \mathrm{~s}^{-1}$, a rate over 20 times that assumed by Lellouch et al. [1994] and Lara et al. [1996]. Furthermore, crossed-beam experiments conducted by Balucani et al. [2000] indicate $\mathrm{CH}_{3} \mathrm{CN}$ to be the likely product
(R127)

$$
\mathrm{N}^{2 \mathrm{~d}}+\mathrm{C}_{2} \mathrm{H}_{4} \rightarrow \mathrm{CH}_{3} \mathrm{CN}+\mathrm{H}
$$

Including (R127) with the Sato et al. [1999] rate produces a profile (Figure 16) that matches observations reasonably well, producing acetonitrile primarily in the upper atmosphere through the scheme

$$
\begin{gather*}
0.5\left(\mathrm{~N}_{2}+h \nu \rightarrow 2 \mathrm{~N}^{2 \mathrm{~d}}\right) \\
\mathrm{N}^{2 \mathrm{~d}}+\mathrm{C}_{2} \mathrm{H}_{4} \rightarrow \mathrm{CH}_{3} \mathrm{CN}+\mathrm{H}  \tag{S33}\\
0.5 \mathrm{~N}_{2}+\mathrm{C}_{2} \mathrm{H}_{4} \rightarrow \mathrm{CH}_{3} \mathrm{CN}+\mathrm{H}
\end{gather*}
$$

[63] Notwithstanding the nominal $\mathrm{C}_{2} \mathrm{H}_{3} \mathrm{CN}$ profile (Figure 16), which presents a stratospheric mixing ratio as high as $3.8 \times 10^{-8}$, observations suggest the lack of significant abundance of acrylonitrile in this region of the atmosphere. $\mathrm{C}_{2} \mathrm{H}_{3} \mathrm{CN}$ has not been identified in the atmosphere of Titan by IRIS or ISO observations. Furthermore, Voyager infrared spectra analysis do not seem to advocate the presence of acrylonitrile condensates in larger abundances than say $\mathrm{C}_{2} \mathrm{~N}_{2}$ or $\mathrm{C}_{4} \mathrm{~N}_{2}$. In the nominal model, acrylonitrile stratospheric production, despite the low rate coefficient for (R156), is clearly dominated by (S23) over (S22). Monks et al. [1993] assume an addi-tion-decomposition process as the favored mechanism of (R156) through analogy with (R155) and (R29). However, a definitive yield for acrylonitrile production was not given as only trace amounts of $\mathrm{C}_{2} \mathrm{H}_{3} \mathrm{CN}$ were identified in the experiment. Thus an excessively large reaction rate for acrylonitrile production through (R156), as well as excessive aerosol opacity in the NUV as discussed in section 5.2, are possible explanations for the large stratospheric abundance of $\mathrm{C}_{2} \mathrm{H}_{3} \mathrm{CN}$ calculated by the model.

### 5.5. Will Ammonia Be Detected?

[64] Ammonia has not been detected in Titan's atmosphere but does serve prominently in Saturn's atmosphere and may have played a significant role in the formation of Titan's present nitrogen inventory [Atreya et al., 1978; Atreya and Wilson, 2001]. Bernard et al. [2003] detected ammonia in their electron discharge simulations of Titan's atmosphere. They correctly point out that the source of ammonia molecules would likely arise through chargedparticle chemistry. Apart from a supply of primordial $\mathrm{NH}_{3}$ from the interior, any ammonia in Titan's strato-

Figure 17. Constituent profiles for various amine species.
sphere will be the result of cosmic-ray ionization of $\mathrm{N}_{2}$, through the mechanism

$$
\begin{gather*}
\mathrm{N}_{2}+G C R \rightarrow \mathrm{~N}^{+}+\mathrm{N}+e^{-} \\
\mathrm{CH}_{4}+\mathrm{N}^{+} \rightarrow \mathrm{HCN}^{+}+\mathrm{H}_{2}+\mathrm{H} \\
\mathrm{CH}_{4}+\mathrm{HCN}^{+} \rightarrow \mathrm{C}_{2} \mathrm{H}_{3}^{+}+\mathrm{NH}_{2}  \tag{S34}\\
\mathrm{~N}_{2}+\frac{\mathrm{NH}_{2}+\mathrm{H} \xrightarrow{\mathrm{M}} \mathrm{NH}_{3}}{\mathrm{CH}_{4} \rightarrow \mathrm{NH}_{3}+\mathrm{N}+\mathrm{H}_{2}+\mathrm{C}_{2} \mathrm{H}_{3}^{+}}+e^{-}
\end{gather*}
$$

[65] However, this mechanism results in an ammonia mole fraction of only $9.6 \times 10^{-13}$ at 120 km (Figure 17). The profile of $\mathrm{NH}_{3}$ indicates a decrease in mole fraction above this level as a result of smaller cosmic ray precipitation, followed by an increasing profile with altitude at higher levels due to the greater influence of precipitating electrons in the upper atmosphere. In this region, electron recombination of ammonium ions, as suggested by Atreya [1986], is the most likely ammonia source. The larger estimate for $\mathrm{NH}_{3}$ by Bernard et al. [2003] is most likely a result of the use of electron discharge as the primary energy source.
[66] The amino radical $\left(\mathrm{NH}_{2}\right)$, produced through (R336a), is responsible for the formation of other amine species, such as $\mathrm{N}_{2} \mathrm{H}_{4}(\mathrm{R} 174 \mathrm{~b})$ and $\mathrm{CH}_{3} \mathrm{NH}_{2}(\mathrm{R} 175)$. Figure 17 shows methylamine $\left(\mathrm{CH}_{3} \mathrm{NH}_{2}\right)$ as the most abundant of the amine species in the stratosphere. However, barring a significant source of primordial ammonia, the low densitites of ammonia may preclude detection by Cassini-Huygens.

### 5.6. Oxygen Species

[67] Buoyed by the recent detection of $\mathrm{H}_{2} \mathrm{O}$ on the giant planets, Feuchtgruber et al. [1997] estimate a water influx of $3-50 \times 10^{5} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$. With the recent detection of $\mathrm{H}_{2} \mathrm{O}$ in Titan's atmosphere, it is evident that this applies to Titan as well. CO is the most abundant oxygen-bearing molecule in Titan's atmosphere. Sensitive millimeter observations have found a uniformly mixed carbon monoxide profile at $\sim 5 \times$ $10^{-5}$ [Muhleman et al., 1984; Gurwell and Muhleman, 1995], although further millimeter observations [Hidayat et al., 1998] and near infrared observations [Noll et al., 1996] have suggested lower abundances with stratospheric deple-
tion. Using a surface CO mole fraction of $5 \times 10^{-5}$ from the Gurwell and Muhleman [1995] finding of $5 \pm 1 \times 10^{-5}$ and an external $\mathrm{H}_{2} \mathrm{O}$ influx of $5 \times 10^{6} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ [Feuchtgruber et al., 1997], abundances are calculated for oxygen-bearing species, shown in Figure 18.
[68] ISO confirmed the existence of water vapor in Titan's atmosphere as Coustenis et al. [1998] found a uniform $\mathrm{H}_{2} \mathrm{O}$ profile at $4 \times 10^{-10}$ consistent with the obtained $\mathrm{H}_{2} \mathrm{O}$ spectrum. However, scaling the Lara et al. [1996] $\mathrm{H}_{2} \mathrm{O}$ model profile by a factor of 0.4 yielded a profile with an $\mathrm{H}_{2} \mathrm{O}$ mole fraction of $8_{-4}^{+6} \times 10^{-9}$ at 400 km to fit the ISO data. The nominal model finds agreement with this observation as shown in Figure 18.
[69] With (R219) as the primary source of $\mathrm{CO}_{2}$, the IRIS carbon dioxide observations argue for an external source of water. Coustenis et al. [1989] found a uniform mole fraction profile of $1.4_{-0.5}^{+0.3} \times 10^{-8}$ to fit IRIS observations, although a linear scaling of a altitude-dependent $\mathrm{CO}_{2}$ profile of Samuelson et al. [1983], yielding a $\mathrm{CO}_{2}$ mole fraction of $1.4 \times 10^{-8}$ at 1.5 mbar where the value of the $\mathrm{CO}_{2}$ contribution function was about $35 \%$ of the peak value at 4 mbar, provided a decent fit. The nominal profile of $\mathrm{CO}_{2}$ is consistent with the IRIS observations, rendering a $\mathrm{CO}_{2}$ mole fraction of $1.4 \times 10^{-8}$ at 4 mbar.
[70] The nominal model predicts much lower abundances for $\mathrm{CH}_{2} \mathrm{CO}$ and $\mathrm{CH}_{3} \mathrm{OH}$ in the stratosphere than Toublanc et al. [1995] as a result of including photolysis which provides

Figure 18. Constituent profiles for various oxygenbearing species with the horizontal bar representing the ISO $\mathrm{H}_{2} \mathrm{O}$ observations based on the Lara et al. [1996] profile, and the box representing the Voyager IRIS $\mathrm{CO}_{2}$ observations.
the main sink for these compounds. Toublanc et al. [1995] refer the absorption cross section of ketene to that of $\mathrm{H}_{2} \mathrm{O}$, although the absorption cross section for $\mathrm{CH}_{2} \mathrm{CO}$ extends past 3000 A [Rabalais et al., 1971], much further than that of $\mathrm{H}_{2} \mathrm{O}(2000 \AA$ A $)$. Furthermore, the nominal model includes the measurement of the $\mathrm{CH}_{3} \mathrm{OH}$ cross section [Wodtke and Lee, 1987], not included in previous models.
[71] However, formaldehyde is predicted to be in greater abundance than in previous models, perhaps near the levels of detection in the stratosphere. $\mathrm{H}_{2} \mathrm{CO}$ is formed through self-reaction of formic acid (HCO), which is produced via pressure-dependent H -attachment to CO , demonstrated in (S29). The calculated $\mathrm{H}_{2} \mathrm{CO}$ mole fraction of $1.0 \times 10^{-9}$ at 4 mbar and the corresponding condensation at the tropopause indicate the possibility of detection of $\mathrm{H}_{2} \mathrm{CO}$ gas and condensate by the GCMS, CIRS, and ACP instruments during the upcoming Cassini-Huygens exploration.
[72] The significant abundance of formaldehyde also suggests the possibility of detection of ethylene oxide $\left(\mathrm{C}_{2} \mathrm{H}_{4} \mathrm{O}\right)$ in Titan's stratosphere. Ethylene oxide was detected in the Titan simulations of Bernard et al. [2003], although they did not detect formaldehyde, presumably a result of the lack of water in their experiments. The isomer of ethylene oxide, acetaldehyde $\left(\mathrm{CH}_{3} \mathrm{CHO}\right)$ is largely produced through the synthesis of methyl radicals and formic acid at higher pressures (R223) and it is redistributed in the oxygen family via reaction with N atoms (R283), released by cosmic rays, and through photolysis. This balance results in a calculated peak $\mathrm{CH}_{3} \mathrm{CHO}$ mole fraction of $4.7 \times 10^{-10}$ at 1 mbar , suggesting possible identification by CassiniHuygens. Ethylene oxide, on the other hand, is formed less efficiently in Titan's atmosphere, produced by the synthesis of ethylene and oxygen atoms [Gaedtke et al., 1973]. Considering this synthesis and the photodissociation of $\mathrm{C}_{2} \mathrm{H}_{4} \mathrm{O}$ [Fleming et al., 1959], ethylene oxide is expected to be present in Titan's atmosphere in abundances of $1-$ 2 orders of magnitude less than acetaldehyde.
[73] A major question involving the distribution of these oxygen-bearing molecules is what the source of carbon monoxide is. Samuelson et al. [1983] suggested a source from the water influx through the mechanism $\mathrm{OH}+\mathrm{CH}_{3} \rightarrow$ $\mathrm{CO}+2 \mathrm{H}_{2}$. However, this was an overall reaction mechanism that was measured by Fenimore [1969]. No laboratory studies [e.g., De Avillez Pereira et al., 1997; Fagerström et al., 1993] have detected CO as a product of this reaction, and no mechanism involving the products of $\mathrm{CH}_{3}+\mathrm{OH}$ forming CO is evident. Lara et al. [1996] calculated an upward flux from the surface of $1.6 \times 10^{6}$ $\mathrm{cm}^{-2} \mathrm{~s}^{-1}$ necessary to maintain an mole fraction of $5 \times$ $10^{-5}$ in equilibrium, which they deem to be unlikely over the course of Titan evolution. Consequently, they have suggested that CO may be provided directly from the influx of micrometeorites, although a typical cometary inventory of CO does not provide enough influx to achieve equilibrium.
[74] Primordial CO remains the most likely source. Bézard et al. [2002] report the likelihood that CO is primordial on Jupiter, on the basis of the CO abundance in the troposphere. The Titan nominal model calculates an upward CO flux of $3.9 \times 10^{6} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ necessary to maintain photochemical equilibrium. Oxygen is lost from the atmosphere through condensation of $\mathrm{CO}_{2}$ and $\mathrm{H}_{2} \mathrm{CO}$,
which combines for an upper limit condensation flux of $4.0 \times 10^{6} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ as determined by the net production rate shown in Table 7. Surficial processes such as outgassing from the interior or irradiation of $\mathrm{CO}_{2}$ and $\mathrm{H}_{2} \mathrm{CO}$ condensates may balance this oxygen loss to the surface, providing a source for CO . Another possibility is that CO is not in equilibrium and was more abundant in Titan's past. Wong et al. [2002] postulate that CO may have been as much as 14 times more abundant after the initial escape stage in Titan's early evolution.

### 5.7. Charged Particles

[75] As shown in section 4.4, ions produced through $\mathrm{N}_{2}$ and $\mathrm{CH}_{4}$ ionization, in particular $\mathrm{N}_{2}^{+}, \mathrm{N}^{+}, \mathrm{CH}_{4}^{+}$, and $\mathrm{CH}_{3}^{+}$ begin the chemical processes that furnish Titan's ionosphere. Figure 19 shows the relative importance of photoionization and photoelectron-impact ionization in the formation of these ions. Electron impact becomes important only below 1000 km , providing an important source in the lower part of this ionospheric region. Five times more $\mathrm{N}_{2}^{+}$ than $\mathrm{N}^{+}$is produced at the peak of ion production through $\mathrm{N}_{2}$ ionization, facilitating the formation of abundant ions $\mathrm{C}_{2} \mathrm{H}_{5}^{+}$and $\mathrm{H}_{2} \mathrm{CN}^{+}$through (S28) and (S29). Comparing these production rates with previous Titan ionosphere models show that the Keller et al. [1992] model provides an $\mathrm{N}_{2}^{+}$production rate peak due to photoionization about three times larger than the nominal profile and about twice as large for $\mathrm{CH}_{4}^{+}$, while Banaszkiewicz et al. [2000] exceeds the nominal rates by 3.5 and 3 times, respectively. The reason for this discrepancy is not evident, but the fact that Banaszkiewicz et al. [2000] consider photoionization at a solar zenith angle of $30^{\circ}$ would certainly be a factor in enhancing their photoionization rates with respect to the nominal model.
[76] The Banaszkiewicz et al. [2000] model shows a significant decrease in the $\mathrm{CH}_{4}$ ionospheric density due to the inclusion of ion chemistry. However, our results indicate that loss of $\mathrm{CH}_{4}$ through chemistry, which is larger than determined by Lara et al. [1999], peaking at $13 \mathrm{~cm}^{-3} \mathrm{~s}^{-1}$ at 1040 km for solar maximum conditions, is more than replenished by the transport of methane from lower altitudes. An increase in the electron flux by a factor of 10 would be necessary to deplete methane whereby the mole fraction decreases with altitude in this region (Figure 20a), but such an increase would result in a peak electron density of $9740 \mathrm{~cm}^{-3}$ (Figure 20b), 24 times larger than observations.
[77] With the influence of EUV radiation on the formation of electrons, the electron density has a strong dependence on solar conditions, as exhibited in Figure 21a. For solar maximum conditions, consistent with those which took place during the Voyager flyby, the nominal model calculates an electron density profile which peaks at a density of $4200 \mathrm{~cm}^{-3}$ at $1060 \mathrm{~km}, 20 \%$ larger than the upper limit of the Bird et al. [1997] radio occultation observations. Considering the differences in production rates, it is not surprising that electron densities of Keller et al. [1992] and Banaszkiewicz et al. [2000] are larger by about $40 \%$ than the nominal model. Assuming electronimpact processes to be scaled for solar minimum and solar moderate conditions, Figure 21a shows a $24 \%$ decrease in the peak electron concentration from solar maximum

Figure 19. Production rates of $\mathrm{N}_{2}^{+}, \mathrm{N}^{+}, \mathrm{CH}_{4}^{+}$, and $\mathrm{CH}_{3}^{+}$ions from photoionization (dashed line), electron impact (dotted line), and the sum of the two processes (solid line).
conditions for moderate solar activity, which should have implications in the INMS observations from the upcoming Cassini-Huygens mission.
[78] Nominal ion densities, calculated for solar maximum conditions, are shown in Figures 21b and 21c. In agreement with Banaszkiewicz et al. [2000] and Keller et al. [1992] the nominal model finds $\mathrm{H}_{2} \mathrm{CN}^{+}$as the major ion above 1000 km . Below this level, a pseudoion representing the collection of larger ions not considered separately in the model is found to dominate, necessitating the kinetic study and modeling of higher order ions.
[79] The most abundant oxidized ion is $\mathrm{H}_{3} \mathrm{O}^{+}$, formed by

$$
\begin{align*}
& 2 \mathrm{CH}_{4} \rightarrow \mathrm{C}_{2} \mathrm{H}_{5}^{+}+\mathrm{H}_{2}+\mathrm{H}+e^{-} \\
& \frac{\mathrm{C}_{2} \mathrm{H}_{5}^{+}+\mathrm{H}_{2} \mathrm{O} \rightarrow \mathrm{H}_{3} \mathrm{O}^{+}+\mathrm{C}_{2} \mathrm{H}_{4}}{-\mathrm{H}_{2} \mathrm{O} \rightarrow \mathrm{H}_{3} \mathrm{O}^{+}+\mathrm{C}_{2} \mathrm{H}_{4}+\mathrm{H}_{2}+\mathrm{H}}+e^{-} \tag{S35}
\end{align*} .
$$

However, the primary function of $\mathrm{H}_{3} \mathrm{O}^{+}$is recycling back to $\mathrm{H}_{2} \mathrm{O}$, through

$$
\begin{equation*}
\mathrm{H}_{3} \mathrm{O}^{+}+\mathrm{HCN} \rightarrow \mathrm{H}_{2} \mathrm{CN}^{+}+\mathrm{H}_{2} \mathrm{O}, \tag{R494}
\end{equation*}
$$

as shown in (S23).
[80] In the stratosphere, an ionosphere develops as well, as a result of cosmic ray ionization of nitrogen. Methane cosmic ray destruction, which is shielded by nitrogen, occurs at a much lesser extent. This cosmic ray deposition, which plays a significant role in nitrile chemistry in the stratosphere as shown previously, results in an electron peak of $1410 \mathrm{~cm}^{-3}$ at 120 km for maximum solar conditions. This value increases to $2010 \mathrm{~cm}^{-3}$ (Figure 4b) with a moderate sun, as cosmic rays diffuse more efficiently during periods of reduced solar activity [Jokipii and Kopriva, 1979]. As products of reactions with larger stable molecules

Figure 20. a) $\mathrm{CH}_{4}$ mole fraction and b) electron density profiles for maximum solar conditions with nominal electron fluxes (solid line) and $10 \times$ nominal electron fluxes (dashed line).
like ethane and acetonitrile, ions like $\mathrm{C}_{4} \mathrm{H}_{7}^{+}(\mathrm{R} 413 \mathrm{~b})$, $\mathrm{C}_{2} \mathrm{H}_{7}^{+}(\mathrm{R} 376 \mathrm{~b}), \mathrm{HCO}^{+}(\mathrm{R} 379), \mathrm{CH}_{3} \mathrm{CNH}^{+}(\mathrm{R} 347)$, and $\mathrm{C}_{5} \mathrm{H}_{5}^{+}(\mathrm{R} 430)$, serve as the gateway to the formation of the large ions which populate Titan's lower ionosphere, as demonstrated by Molina-Cuberos et al. [1999]. Ion clusters, as stated before, may also play a significant role in the lower ionosphere.

## 6. Conclusions

[81] The results of a one-dimensional photochemical model of Titan's neutral constituents and charged particles have been reported. This model contains updated chemistry and an extensive treatment of dissociation processes from solar photons at $50-3000 \AA$ and electrons at $15-1000 \mathrm{eV}$, as well as parameterization of processes including galactic cosmic rays, magnetospheric electrons, and opacity provided by fractal haze particles.
[82] A test of various eddy diffusion profiles has revealed a profile with a homopause level of 850 km to provide the best fit to IRIS and ISO stratospheric observations as well as UVS observations in the upper atmosphere. With such a profile, fitted with the assumption of methane supersaturation near the tropopause, as analyzed by the Samuelson et al. [1997] study, the nominal model provides a good fit for the bulk of Titan stratospheric observations and provides a reasonable fit for most of the Voyager UVS reanalysis
observations, an improvement over previous models. In this model, loss of HCN due to polymerization to Titan haze is not required to match observations. The profile of Lara et al. [2002], derived with a more extreme scenario of tropospheric methane supersaturation suggested by Courtin et al. [1995], was also tested. This profile, although providing a good fit of $\mathrm{CH}_{4}$ and HCN observations, significantly underestimates stratospheric $\mathrm{CH}_{3} \mathrm{C}_{2} \mathrm{H}$ and overestimates $\mathrm{C}_{4} \mathrm{H}_{2}$ in the lower and middle atmosphere. The nominal profile, assuming opacity provided by fractal haze particles from Lebonnois et al. [2001], underpredicts the $\mathrm{C}_{3} \mathrm{H}_{8}$ stratospheric mole fraction by about a factor of two, while rendering profiles for $\mathrm{HC}_{3} \mathrm{~N}$ and $\mathrm{C}_{2} \mathrm{H}_{3} \mathrm{CN}$ that are not consistent with the lack of firm detection by the IRIS equatorial observations. Assuming Mie haze opacities, these profiles fall much more in line with what has and has not been observed, suggesting that the opacities for the fractal case used in the model may be too large.
[83] Dynamics is certain to play an important role in the distribution of Titan's constituents and the effect of dynamical processes should certainly be explored. However,

Figure 21. Density distribution of ions in Titan's upper ionosphere.
considering the limitations of existing observations, the uncertainties in other parameters such as aerosol opacity, and the results of the model, it is not possible to rule out the possibility that the globally averaged distribution of Titan's constituents can be accurately and simultaneously described with a single eddy-diffusion profile.
[84] Considering the differences in the expected solar flux during the upcoming Cassini-Huygens mission and the more enhanced solar flux during the Voyager flyby of Titan, sensitivity to variations in solar flux during the course of solar cycle has been explored. With the large chemical lifetimes of most of the stable constituents in Titan's atmosphere, only $\mathrm{C}_{4} \mathrm{H}_{2}$ demonstrated significant sensitivity among likely observed species, with stratospheric densities for moderate solar conditions reduced by about $60 \%$ from solar maximum conditions and a variation of a factor of three from solar maximum to solar minimum.
[85] The profile of $\mathrm{C}_{6} \mathrm{H}_{6}$ is improved on the basis of ISO observations [Coustenis et al., 2003], compared with previous studies by the authors [Wilson et al., 2003]. The inclusion of haze opacity sharply reduces the amount of benzene photolysis, the primary sink for $\mathrm{C}_{6} \mathrm{H}_{6}$ in the stratosphere. With this inclusion, the profile of $\mathrm{C}_{6} \mathrm{H}_{6}$ under nominal Titan temperature dependency matches the ISO observations and suggests a mechanism for haze production peaking at 180 km .
[86] A mechanism for the formation of $\mathrm{CH}_{3} \mathrm{C}_{2} \mathrm{H}$ is proposed with the aid of the kinetic measurements of Canosa et al. [1997]. Assuming a branching ratio of 0.5 for methylacetylene production through $\mathrm{CH}+\mathrm{C}_{2} \mathrm{H}_{4}$, the profile of $\mathrm{CH}_{3} \mathrm{C}_{2} \mathrm{H}$ finds good agreement with observations, over the results of previous models. In agreement with previous models exploring Titan's ionosphere, the dominant ion at the electron peak is found to be $\mathrm{H}_{2} \mathrm{CN}^{+}$, with larger ions making up the bulk of Titan's ionosphere below 1000 km . The peak of electron density is found to be $4200 \mathrm{~cm}^{-3}$, a $20 \%$ enhancement over the observations of Bird et al. [1997]. The electron peak density is expected to be reduced by about $24 \%$ for moderate solar conditions. CassiniHuygens will encounter variations in the magnetospheric input into the ionosphere. Any major enhancement of magnetospheric electrons over what was found by Voyager should affect the electron density above 1150 km , with no major effect on atmospheric neutrals.
[87] The Cassini-Huygens mission will seek to answer many of the questions explored in this study, among many others. Results from this model indicate the possible detection of $\mathrm{H}_{2} \mathrm{CO}$ and $\mathrm{C}_{2} \mathrm{H}_{3} \mathrm{CN}$ by the Composite Infrared Spectrometer (CIRS) and the Gas Chromatograph Mass Spectrometer (GCMS), although acrylonitrile abundances may be overpredicted due to chemistry or opacity assumptions. Benzene, already tentatively detected by ISO [Coustenis et al., 2003] is predicted to be observed by these instruments, and the analysis of aerosols by the Aerosol Collector Pyrolyser (ACP) will enhance what we know about the composition and formation processes of Titan's aerosols. Furthermore, observations of constituents like $\mathrm{C}_{2} \mathrm{H}_{2}$ and $\mathrm{CH}_{3} \mathrm{C}_{2} \mathrm{H}$ by the Ultraviolet Imaging Spectrograph (UVIS) and the Ion and Neutral Mass Spectrometer (INMS) will further increase our understanding of the chemical and diffusive processes in the upper atmosphere. This model in conjunction with data
can be used as a helpful tool in furthering the understanding of Titan's atmosphere.

## Appendix A: Finite Differencing and Matrix Solver

[88] The photochemical model solves the continuitydiffusion equation in spherical coordinates, accounting for condensation,

$$
P_{i}-L_{i}-\gamma_{i}=\frac{1}{r^{2}} \frac{\partial\left(r^{2} \Phi_{i}\right)}{\partial r}
$$

where $\Phi_{i}$ is taken to be the flux of species $i$ in the radial direction. Multiplying both sides by $r^{2}$ and integrating over the interval $\left[\tilde{r}_{1}, \tilde{r}_{2}\right]$ yields

$$
\int_{\tilde{r}_{2}}^{\tilde{r}_{1}} \frac{\partial\left(r^{2} \Phi_{i}\right)}{\partial r} d r=\int_{\tilde{r}_{2}}^{\tilde{r}_{1}} r^{2}\left[P_{i}-L_{i}-\gamma_{i}\right] d r
$$

or

$$
\begin{aligned}
\tilde{r}_{1}^{2} \Phi_{i}\left(\tilde{r}_{1}\right)-\tilde{r}_{2}^{2} \Phi_{i}\left(\tilde{r}_{2}\right)= & \frac{1}{3} \tilde{r}_{1}^{3}\left[P_{i}(r)-L_{i}(r)-\gamma_{i}(r)\right] \\
& -\frac{1}{3} \tilde{r}_{2}^{3}\left[P_{i}(r)-L_{i}(r)-\gamma_{i}(r)\right]
\end{aligned}
$$

assuming $P_{i}-L_{i}-\gamma_{i}$ constant over the interval $\left[\tilde{r}_{1}, \tilde{r}_{2}\right]$. Equations (2) and (4) indicate that $n=n\left(\xi_{1}^{A}, \ldots, \xi_{S}^{A}\right)$ where the $\xi_{1}^{A}, \ldots, \xi_{S}^{A}$ are the S abundant species which affect the mean molecular weight, defined as species with a mole fraction greater than $10^{-3}$ for a particular level $r$. So, $\Phi_{i}=$ $\Phi_{i}\left(n\left(\xi_{1}^{A}, \ldots, \xi_{S}^{A}\right), \xi_{i}\right)$ and the $P_{i}, L_{i}$, and $\gamma_{i}$ are functions of $n\left(\xi_{1}^{A}, \ldots, \xi_{S}^{A}\right)$ and the $\xi_{1}, \ldots, \xi_{N}$ for M species and N atmospheric levels. Charged particles are assumed to be governed solely by chemistry, with $\Phi_{i}=0$, and the assumption of charge neutrality

$$
n_{e}=\sum_{i} n_{i}
$$

where $n_{e}$ is the electron density and $n_{i}$ is the density of each ion $i$.
[89] This system of equations is set up through finite differencing on a grid where the fluxes are expressed in terms of its values at $\tilde{r}_{1}=r_{i+1 / 2}$ and $\tilde{r}_{2}=r_{i-1 / 2}$, assuming that they are linear in the intervals $[i-1, i]$ and $[i, i+1]$, while the chemical terms are expressed at $r=r_{i}$. Thus for a quantity Q ,

$$
Q\left(\tilde{r}_{1}\right)=\frac{Q\left(r_{i+1}\right)+Q\left(r_{i}\right)}{2}, Q\left(\tilde{r}_{2}\right)=\frac{Q\left(r_{i}\right)+Q\left(r_{i-1}\right)}{2}
$$

while

$$
\frac{\partial Q\left(\tilde{r}_{1}\right)}{\partial z}=\frac{Q\left(r_{i+1}\right)-Q\left(r_{i}\right)}{r_{i+1}-r_{i}}, \frac{\partial Q\left(\tilde{r}_{2}\right)}{\partial z}=\frac{Q\left(r_{i}\right)-Q\left(r_{i-1}\right)}{r_{i}-r_{i-1}} .
$$

At the lower boundary, the mixing ratios $\xi_{1}, \ldots, \xi_{N}$ and number density $n$ are set to zero or their lower boundary
conditions, shown in Table 5, where $n$ is described by equation (5). At the upper boundary, the flux equations are finite differenced where, using equation (2),

$$
\begin{aligned}
\Phi_{i}\left(\tilde{r}_{N}\right)= & -\left[D_{i}\left(\tilde{r}_{N}\right)+K\left(\tilde{r}_{N}\right)\right] n\left(\tilde{r}_{N}\right) \frac{\partial \xi_{i}\left(\tilde{r}_{N}\right)}{\partial z} \\
& -D_{i}\left(\tilde{r}_{N}\right) \xi\left(\tilde{r}_{N}\right)\left[\frac{\partial n\left(\tilde{r}_{N}\right)}{\partial z}+n\left(\tilde{r}_{N}\right)\left(\frac{1}{T\left(\tilde{r}_{N}\right)} \frac{\partial T\left(\tilde{r}_{N}\right)}{\partial z}\right.\right. \\
& \left.\left.+\frac{1}{H_{i}\left(\tilde{r}_{N}\right)}\right)\right] \\
= & \beta_{i}^{\Phi}
\end{aligned}
$$

where for quantity Q ,

$$
Q\left(\tilde{r}_{N}\right)=\frac{Q\left(r_{N}\right)+Q\left(r_{N-1}\right)}{2}, \frac{\partial Q\left(\tilde{r}_{N}\right)}{\partial z}=\frac{Q\left(r_{N}\right)-Q\left(r_{N-1}\right)}{r_{N}-r_{N-1}}
$$

and $\beta_{i}^{\Phi}=$ flux boundary condition for species $i$. For species H and $\mathrm{H}_{2}$, the velocity equations at the boundary from equation (15) are expressed as

$$
\begin{aligned}
w_{i}\left(\tilde{r}_{N}\right)= & -\left[D_{i}\left(\tilde{r}_{N}\right)+K\left(\tilde{r}_{N}\right)\right] \frac{\partial \ln \left(\xi_{i}\left(\tilde{r}_{N}\right)\right)}{\partial z} \\
& -D_{i}\left(\tilde{r}_{N}\right)\left[\frac{\partial \ln \left(n\left(\tilde{r}_{N}\right)\right)}{\partial z}+\left(\left(1+\alpha_{i}\left(\tilde{r}_{N}\right)\right) \frac{1}{T\left(\tilde{r}_{N}\right)} \frac{\partial T\left(\tilde{r}_{N}\right)}{\partial z}\right.\right. \\
& \left.\left.+\frac{1}{H_{i}\left(\tilde{r}_{N}\right)}\right)\right] \\
= & \beta_{i}^{w}
\end{aligned}
$$

where for quantity Q ,

$$
\frac{\partial \ln \left(Q_{i}\left(\tilde{r}_{N}\right)\right)}{\partial z}=\frac{1}{Q_{i}\left(\tilde{r}_{N}\right)} \frac{\partial Q_{i}\left(\tilde{r}_{N}\right)}{\partial z}=\frac{\ln \left(Q_{i}\left(r_{N}\right)\right)-\ln \left(Q_{i}\left(r_{N-1}\right)\right)}{r_{N}-r_{N-1}}
$$

and $\beta_{i}^{w}=$ velocity boundary condition for species $i$.
[90] Meanwhile, equations (3) and (4) can be combined with expression (1) and expressed in terms of $r_{i-1}, r_{i}$, and $r_{i+1}$ to calculate the total density

$$
\begin{gather*}
r^{2} \nabla_{r} p=-r^{2} n m g \\
\int_{\tilde{r}_{2}}^{\tilde{r}_{1}} \frac{\partial}{\partial r}\left(r^{2} p\right) d r=-G M \int_{\tilde{r}_{2}}^{\tilde{r}_{1}} \frac{r^{2} n m}{r^{2}} d r \\
\tilde{r}_{1}^{2} p\left(\tilde{r}_{1}\right)-\tilde{r}_{2}^{2} p\left(\tilde{r}_{2}\right)=-G M n(r) m(r)\left[\tilde{r}_{1}-\tilde{r}_{2}\right] \tag{A1}
\end{gather*}
$$

or, taking condensation into account,

$$
\tilde{r}_{1}^{2} p\left(\tilde{r}_{1}\right)-\tilde{r}_{2}^{2} p\left(\tilde{r}_{2}\right)=-G M\left[n(r) m(r)-\gamma^{c}\right]\left[\tilde{r}_{1}-\tilde{r}_{2}\right]
$$

where

$$
p\left(\tilde{r}_{1}\right)=\frac{n\left(\tilde{r}_{1}\right) k T\left(\tilde{r}_{1}\right)}{f\left(\tilde{r}_{1}\right)}, p\left(\tilde{r}_{2}\right)=\frac{n\left(\tilde{r}_{2}\right) k T\left(\tilde{r}_{2}\right)}{f\left(\tilde{r}_{2}\right)}
$$

$$
\gamma^{c}=\left\{\begin{array}{c}
{\left[n m(r)-n m^{s a t}(r)\right]^{p}, m(r) m^{s a t}(r)} \\
-\left[n m^{s a t}(r)-n m(r)\right]^{p}, m^{s a t}(r) m(r)
\end{array},\right.
$$

and

$$
m(r)=\sum_{j}^{S} \xi_{j}^{A}(r) m\left(\xi_{j}^{A}(r)\right)
$$

At the boundary $\left(r=r_{N}\right)$, since $\tilde{r}_{1}=R_{0}+z-\frac{1}{2} \Delta z$ and $\tilde{r}_{2}=$ $R_{0}+z+\frac{1}{2} \Delta z$, one can write in equation (A1) $\tilde{r}_{2}=2\left(R_{0}+z\right)-$ $\tilde{r}_{1}$ or $\tilde{r}_{2}=2 r_{N}-\tilde{r}_{1}$, where $\tilde{r}_{1}=\frac{r_{N}+r_{N-1}}{2}$, and as follows, $n\left(\tilde{r}_{2}\right)=2 n\left(r_{N}\right)-n\left(\tilde{r}_{1}\right), T\left(\tilde{r}_{2}\right)=2 T\left(r_{N}\right)-\stackrel{2}{T}\left(\tilde{r}_{1}\right)$, and $f\left(\tilde{r}_{2}\right)=2 f\left(r_{N}\right)$ $2 f\left(r_{N}\right)-f\left(\tilde{r}_{1}\right)$.
[91] To solve this set of $T=(N) \times(M+1)$ nonlinear equations, the set can be linearized by expressing the equations as

$$
f_{i}\left(\xi_{1}, \ldots, \xi_{M}, n\right)=0
$$

expanding $f_{i}$ in a Taylor series expansion, and dropping the higher order terms,

$$
\begin{aligned}
f_{i}\left(\xi_{1}\right. & \left.+\Delta \xi_{1}, \ldots, \xi_{M}+\Delta \xi_{M}, \ldots, n+\Delta n\right) \\
= & 0 \\
= & f_{i}\left(\xi_{1}, \ldots, \xi_{M}, n\right) \\
& +\sum_{j}^{M} \frac{\partial f\left(\xi_{1}, \ldots, \xi_{M}, n\right)}{\partial \xi_{j}} \Delta \xi_{j}+\frac{\partial f\left(\xi_{1}, \ldots, \xi_{M}, n\right)}{\partial n} \Delta n
\end{aligned}
$$

This results in the formation of a Jacobian matrix

$$
\mathbf{J}=\left[\begin{array}{ccccc}
\frac{\partial f_{1}}{\partial \xi_{1}} & \cdot & \cdot & \cdot & \frac{\partial f_{1}}{\partial \xi_{M}}
\end{array} \frac{\partial f_{1}}{\partial n} \begin{array}{cccc}
\cdot & \cdot & \cdot & \cdot \\
\frac{\partial \dot{f}_{T}}{\partial \xi_{1}} & \cdot & \cdot & \cdot \\
\frac{\partial \dot{f}_{T}}{\partial \xi_{M}} & \frac{\partial \dot{f}_{T}}{\partial n}
\end{array}\right], \Delta \mathbf{x}=\left[\begin{array}{c}
\Delta \xi_{1} \\
\cdot \\
\cdot \\
\dot{\xi_{M}} \\
\Delta n
\end{array}\right]
$$

such that

$$
\mathrm{J} \cdot \Delta \mathbf{x}=-\mathbf{f}
$$

The Jacobian can then be inverted to solve for the $\Delta \mathbf{x}=$ $\left(\Delta \xi_{1}, \ldots, \Delta \xi_{M}, \Delta n\right)$, which is then added to the $\mathbf{x}=\left(\xi_{1}, \ldots\right.$, $\left.\xi_{M}, n\right)$ and the following equation is solved iteratively

$$
\mathbf{x}^{(k+1)}=\mathbf{x}^{(k)}-\left[\mathbf{J}^{(k)}\right]^{-1} \mathbf{f}^{(k)}
$$

until $\Delta \mathbf{x}=\mathbf{x}^{(k+1)}-\mathbf{x}^{(k)}$ falls below the tolerance level. The Jacobian matrix is solved by the Crout-LU decomposition method with scaled partial pivoting [Yakowitz and Szidarovszky, 1989], optimized for banded matrices.

## Tables

Table 1. List of Neutral and Ionic Compounds Used in the Model

| Neutrals |  |  |
| :--- | :--- | :--- |
| H | atomic hydrogen | Ions |
| $\mathrm{H}_{2}$ | molecular hydrogen | $\mathrm{H}_{2}{ }^{+}$ |
| C | atomic carbon | $\mathrm{H}_{3}{ }^{+}$ |
| CH | methylidyne | $\mathrm{H}_{2} \mathrm{O}^{+}$ |
| ${ }^{1} \mathrm{CH}_{2}$ | excited-state methylene | $\mathrm{H}_{3} \mathrm{O}^{+}$ |
| ${ }^{3} \mathrm{CH}_{2}$ | ground-state methylene | $\mathrm{HCO}^{+}$ |
| $\mathrm{CH}_{3}$ | methyl radical | $\mathrm{CH}_{3}{ }^{+}$ |
| $\mathrm{CH}_{4}$ | methane | $\mathrm{CH}_{4}{ }^{+}$ |
| $\mathrm{C}_{2}$ | molecular carbon | $\mathrm{CH}_{5}{ }^{+}$ |
| $\mathrm{C}_{2} \mathrm{H}^{2}$ | ethynyl radical | $\mathrm{C}_{2} \mathrm{H}_{2}{ }^{+}$ |
| $\mathrm{C}_{2} \mathrm{H}_{2}$ | acetylene | $\mathrm{C}_{2} \mathrm{H}_{3}{ }^{+}$ |
| $\mathrm{C}_{2} \mathrm{H}_{3}$ | vinyl radical | $\mathrm{C}_{2} \mathrm{H}_{4}{ }^{+}$ |
| $\mathrm{C}_{2} \mathrm{H}_{4}$ | ethylene | $\mathrm{C}_{2} \mathrm{H}_{5}{ }^{+}$ |
| $\mathrm{C}_{2} \mathrm{H}_{5}$ | ethyl radical | $\mathrm{C}_{2} \mathrm{H}_{6}{ }^{+}$ |
| $\mathrm{C}_{2} \mathrm{H}_{6}$ | ethane | $c-\mathrm{C}_{3} \mathrm{H}_{3}{ }^{+}$ |
| $\mathrm{C}_{3} \mathrm{H}_{2}$ | propadienylidene | $\mathrm{C}_{3} \mathrm{H}_{5}{ }^{+}$ |
| $\mathrm{C}_{3} \mathrm{H}_{3}$ | propargyl radical | $\mathrm{C}_{4} \mathrm{H}_{2}{ }^{+}$ |
| $\mathrm{CH}_{3} \mathrm{C}_{2} \mathrm{H}$ | methylacetylene | $\mathrm{C}_{4} \mathrm{H}_{3}{ }^{+}$ |
| $\mathrm{CH}_{2} \mathrm{CCH}_{2}$ | allene | $\mathrm{C}_{6} \mathrm{H}_{7}{ }^{+}$ |
| $\mathrm{C}_{3} \mathrm{H}_{5}$ | allyl radical | $\mathrm{N}^{+}$ |
| $\mathrm{C}_{3} \mathrm{H}_{6}$ | propylene |  |
| $\mathrm{C}_{3} \mathrm{H}_{7}$ | isopropyl radical | $\mathrm{NH}^{+}$ |
| $\mathrm{C}_{3} \mathrm{H}_{8}$ | propane | $\mathrm{N}_{2} \mathrm{H}^{+}$ |
| $\mathrm{C}_{4} \mathrm{H}$ |  | $\mathrm{NH}_{2}{ }^{+}$ |
| $\mathrm{C}_{4} \mathrm{H}_{2}$ | diacetylene |  |

| $\mathrm{C}_{4} \mathrm{H}_{2}{ }^{*}$ | excited-state diacetylene | $\mathrm{NH}_{4}{ }^{+}$ |
| :---: | :---: | :---: |
| $\mathrm{C}_{4} \mathrm{H}_{3}$ |  | $\mathrm{CN}^{+}$ |
| $\mathrm{C}_{4} \mathrm{H}_{4}$ | vinylacetylene | $\mathrm{HCN}^{+}$ |
| $\mathrm{C}_{4} \mathrm{H}_{5}$ | 1-butyn-3-yl radical | $\mathrm{H}_{2} \mathrm{CN}^{+}$ |
| $\mathrm{C}_{4} \mathrm{H}_{6}$ | 1,3-butadiene | $\mathrm{C}_{\mathrm{x}} \mathrm{H}_{\mathrm{y}}{ }^{+}$ |
| $\mathrm{C}_{4} \mathrm{H}_{8}$ | 1-butene | $\mathrm{C}_{\mathrm{x}} \mathrm{H}_{\mathrm{y}} \mathrm{N}_{\mathrm{z}}{ }^{+}$ |
| $\mathrm{C}_{4} \mathrm{H}_{10}$ | n-butane | $\mathrm{C}_{\mathrm{x}} \mathrm{H}_{\mathrm{y}} \mathrm{O}_{\mathrm{z}}{ }^{+}$ |
| $\mathrm{C}_{6} \mathrm{H}$ |  | $\mathrm{N}_{\mathrm{x}}{ }^{+}$ |
| $\mathrm{C}_{6} \mathrm{H}_{2}$ | triacetylene |  |
| $\mathrm{C}_{6} \mathrm{H}_{4}$ | benzyne |  |
| $\mathrm{n}-\mathrm{C}_{6} \mathrm{H}_{4}$ | linear- $\mathrm{C}_{6} \mathrm{H}_{4}$ |  |
| $\mathrm{C}_{6} \mathrm{H}_{5}$ | phenyl radical |  |
| $\mathrm{n}-\mathrm{C}_{6} \mathrm{H}_{5}$ | linear- $\mathrm{C}_{6} \mathrm{H}_{5}$ |  |
| $\mathrm{C}_{6} \mathrm{H}_{6}$ | benzene |  |
| $\mathrm{n}-\mathrm{C}_{6} \mathrm{H}_{6}$ | linear- $\mathrm{C}_{6} \mathrm{H}_{6}$ |  |
| $\mathrm{C}_{6} \mathrm{H}_{7}$ | cyclized- $\mathrm{C}_{6} \mathrm{H}_{7}$ |  |
| n- $\mathrm{C}_{6} \mathrm{H}_{7}$ | linear- $\mathrm{C}_{6} \mathrm{H}_{7}$ |  |
| $\mathrm{C}_{8} \mathrm{H}_{2}$ | tetraacetylene |  |
| $\mathrm{N}^{4 \mathrm{~s}}$ | ground-state atomic nitrogen |  |
| $\mathrm{N}^{2 \mathrm{~d}}$ | excited-state atomic nitrogen |  |
| $\mathrm{N}_{2}$ | molecular nitrogen |  |
| NH | imidogen |  |
| $\mathrm{NH}_{2}$ | amino radical |  |
| $\mathrm{NH}_{3}$ | ammonia |  |
| $\mathrm{N}_{2} \mathrm{H}_{2}$ | diimide |  |
| $\mathrm{N}_{2} \mathrm{H}_{3}$ | hydrazinyl radical |  |
| $\mathrm{N}_{2} \mathrm{H}_{4}$ | hydrazine |  |
| CN | cyano radical |  |
| HCN | hydrogen cyanide |  |
| $\mathrm{H}_{2} \mathrm{CN}$ | methylene-amidogen radical |  |
| CHCN |  |  |
| $\mathrm{CH}_{2} \mathrm{CN}$ | cyanomethyl radical |  |

| $\mathrm{CH}_{3} \mathrm{CN}$ | acetonitrile |  |
| :---: | :---: | :---: |
| $\mathrm{C}_{2} \mathrm{~N}_{2}$ | cyanogen |  |
| $\mathrm{HC}_{2} \mathrm{~N}_{2}$ |  |  |
| $\mathrm{C}_{3} \mathrm{~N}$ | cyanoethynyl radical |  |
| $\mathrm{HC}_{3} \mathrm{~N}$ | cyanoacetylene |  |
| $\mathrm{H}_{2} \mathrm{C}_{3} \mathrm{~N}$ | cyanovinyl radical |  |
| $\mathrm{C}_{2} \mathrm{H}_{3} \mathrm{CN}$ | acrylonitrile |  |
| $\mathrm{C}_{4} \mathrm{~N}_{2}$ | dicyanoacetylene |  |
| $\mathrm{O}^{3 \mathrm{p}}$ | ground-state atomic oxygen |  |
| $\mathrm{O}^{1 \mathrm{~d}}$ | excited-state atomic oxygen |  |
| OH | hydroxyl radical |  |
| $\mathrm{H}_{2} \mathrm{O}$ | water |  |
| CO | carbon monoxide |  |
| $\mathrm{CO}_{2}$ | carbon dioxide |  |
| HCO | formyl radical |  |
| $\mathrm{H}_{2} \mathrm{CO}$ | formaldehyde |  |
| $\mathrm{CH}_{2} \mathrm{OH}$ | hydroxymethyl radical |  |
| $\mathrm{CH}_{3} \mathrm{O}$ | methoxy radical |  |
| $\mathrm{CH}_{3} \mathrm{OH}$ | methanol |  |
| $\mathrm{CH}_{2} \mathrm{CO}$ | ketene |  |
| $\mathrm{CH}_{3} \mathrm{CO}$ | acetyl radical |  |
| $\mathrm{CH}_{3} \mathrm{CHO}$ ethylene oxide |  |  |
| $\mathrm{C}_{2} \mathrm{H}_{4} \mathrm{O}$ | oxirane |  |

Table 2. Observations of Constituents in Titan's Atmosphere

| Species | Altitude, km | Instrument | Observation | References |
| :---: | :---: | :---: | :---: | :---: |
| $\mathrm{CH}_{4}{ }^{\text {a }}$ | 1400 | Voyager UVS | $20 \pm 2 \%$ | Strobel et al. [1992] |
|  | 1130 |  | $8 \pm 3 \%$ | Smith et al. [1982] |
|  | 1000 |  | $6 \pm 1 \%$ | Smith et al. [1982] |
